Platelet concentrates cryopreserved using DMSO are in use clinically as an alternative to conventional liquid stored platelets. However, this use is limited because the technique is relatively time consuming, laborious, and quite costly.[386] In addition, they must be washed before transfusion to remove DMSO, which can produce clinical side effects such as nausea, vomiting, and local vasospasm. Frozen platelets have generally been reserved for banking of autologous platelets from patients with acute leukemia who have become heavily alloimmunized and, hence, refractory to allogeneic platelet products. The efficacy of cryopreserved and liquid-preserved platelets has also been compared in cardiopulmonary bypass surgery.[398] Cryopreserved platelets appeared effective in minimizing blood loss and the need to transfuse blood products. However, these authors suggest that procoagulant activity, rather than common in vitro measures of platelet quality (aggregation, hypotonic stress, etc.), more accurately reflects the ability of cryopreserved platelets to maintain hemostasis. This argument has been further buttressed by data showing that thawed cryopreserved platelets, while possessing diminished capacity for aggregation to common agonists, generate significantly higher levels of thromboxane A2, a potent vasoconstrictor and platelet aggregator, when compared with conventionally stored platelet controls.[399]

DMSO Cryopreservation with Platelet-Stabilizing Agents

Solutions containing platelet-stabilizing agents (e.g., ThromboSol [Life Cell, The Woodlands, Tx.] containing amiloride, adenosine, and nitroprusside) have been developed that allow reducing the DMSO concentration while preserving recovery and survival on transfusion.[400,401] These solutions allow using only 2% DMSO while better maintaining platelet viability and both in vitro and in vivo function. Other investigators have reported the use of epinephrine[402] and varying combinations of Composol PS (Fresenius Kabi AG, Bad Homburg, Germany) and plasma[403] with DMSO that likewise demonstrate acceptable post-thaw in vitro and in vivo characteristics. Platelet cryopreservation using a combination of trehalose, a simple disaccharide sugar, supplemented with phosphate demonstrates preservation of the platelet plasma membrane, metabolic activity, and aggregation response to thrombin following cryopreservation.[404]

Synthetic Platelet Alternatives

Arg-Gly-Asp (RGD)–Based Platelet Substitutes

Several approaches to the creation of "platelet substitutes"—hemostatically active synthetic products that do not rely on the use of platelets or platelet fragments, yet possess properties similar to intact platelets—have been attempted. One such approach makes use of peptides containing Arg-Gly-Asp (RGD) sequences that mimic those normally found on fibrinogen. RGD motifs present on fibrinogen act as the primary binding sites for the platelet integrin on the surface glycoprotein GPIIb-IIIa and are responsible for the cross-linking of activated platelets that results in formation of the primary platelet plug at the site of vascular injury. Because binding occurs only to activated GPIIb-IIIa molecules, reactivity is limited to activated platelets normally present only at sites of vascular disruption. Peptides containing RGD sequences have been successfully covalently bound to RBCs.[405] The clinical application of this method, however, appears doubtful at present; although RBCs coated with RGD-bearing peptides are able to cause platelet agglutination in vitro, in vivo studies have failed to demonstrate adequate hemostatic efficacy.[406]

Fibrinogen-Coated Albumin Microcapsules

A second approach makes use of fibrinogen adsorbed onto carrier albumin microcapsules. At least two commercial formulations are in development—Synthocytes (Quadrant Healthcare, Nottingham, U.K.) and Haemaplax (Haemostatix, Leicester, U.K.). These products, also referred to more generically as fibrinogen-coated albumin microcapsules (FAMs), readily stimulate platelet activation and aggregation in vitro[407] and shorten bleeding time (BT) and reduce bleeding in thrombocytopenic rabbit models.[408] The results of human phase IIa trials using Synthocytes have not yet been reported.[409]

Liposome-Based Strategies

A third strategy has been to use liposome-based agents bearing either covalently bound fibrinogen or platelet glycoproteins such as recombinant GPIbα,[410] or infusion of procoagulant liposomes with activated factor Xa.[379] In vitro tests have shown that GPIbα-liposomes can mediate vWF accumulation on subendothelial tissues and enhance platelet function. Intravenous infusions of procoagulant liposomes in conjunction with activated factor Xa have been studied in hemophiliac dogs; however, this strategy had unacceptable toxic effects. Other platelet substitutes being studied include inert polyacrylonitrile beads coated with fibrinogen.[378]

Although many of these products face long research and development times, problems with current platelet preparations and antigenicity of certain formulations of thrombopoietic cytokines are encouraging many companies to further pursue development of these products.

THROMBOPOIETIC GROWTH FACTORS

Clinical Success of Recombinant Hematopoietic Growth Factors

Hematopoietic growth factors have enjoyed tremendous clinical successes as witnessed by the widespread use of recombinant erythropoietin to treat anemias due to chemotherapy,[411] myelodysplasia,[412] or chronic kidney diseases[413] and the use of granulocyte-colony stimulating factor[414] (G-CSF) in the treatment of patients with hematologic disorders[415] and infectious diseases.[416,417] Their use in clinical medicine has been to help limit exposure of patients to allogenic blood components and the short- and long-term adverse effects—such as platelet alloimmunization and iron overload[418]—that can occur with chronic exposure. The isolation, characterization, and subsequent synthesis of erythropoietin by recombinant technology, for example, has reduced the need for chronic RBC transfusions in certain patient populations. A similar agonist that would stimulate endogenous production of platelets in thrombocytopenic hosts has yet to be developed, although the current limitations and risks inherent in plate-

let transfusion therapy continue to drive development of such an agent.[419]

Potential Benefits of Recombinant Thrombopoietic Growth Factors

Thrombopoietic growth factors have the potential to stimulate platelet apheresis donors, to increase stem cell harvest yields, and to expand progenitor cells ex vivo.[420] There are rapid developments in the use of growth factors including FLT-3 ligand, c-Mpl ligand (thrombopoietin), and various combinations of growth factors. Interleukin-11 (IL-11), a 199-amino-acid protein coded for on chromosome 19q, directly stimulates the proliferation of hematopoietic stem cells and megakaryocyte progenitors and induces increased megakaryocyte maturation. A commercial form of IL-11 was approved by the FDA in 1997 for preventing severe thrombocytopenia in patients receiving myelosuppressive chemotherapy. However, IL-11 effects on platelet production are modest, and it is not recommended for patients with myeloid leukemias.[421]

Growth Factors and Megakaryocytopoiesis

Megakaryocytopoiesis—the production of platelets by bone marrow megakaryocytes—is under the control of a large host of cytokines and growth factors including IL-1, IL-3, IL-6, IL-11, erythropoietin, granulocyte-macrophage colony stimulating factor (GM-CSF), fibroblast growth factor (FGF), stem cell factor (SCF), leukemia inhibitory factor (LIF), and thrombopoietin.[422,423] Of these, thrombopoietin (TPO), a relatively lineage-specific trophic factor, is the most potent.[424] Although TPO messenger RNA (mRNA) has been detected in numerous organs, particularly the liver and kidney,[425,426] data from liver transplantation studies, in which pretransplant undetectable TPO levels were restored to normal following successful transplantation, suggest that essentially all TPO is synthesized in the liver.[427] In normal individuals, TPO production appears relatively constant[428]; variations in plasma concentration are due to binding, internalization, and subsequent degradation of TPO by c-Mpl[429] (the thrombopoietin receptor) expressing cells, such as hematopoietic stem cells, megakaryocytes, and platelets. Clinically, this results in an inverse relationship between circulating platelet counts and plasma TPO concentration. The thrombocytopenia associated with chemotherapy, for example, results in a net loss of MPL-expressing cells, resulting in elevated TPO levels due to diminished consumption.[430] This normal inverse relationship, however, is disrupted in a variety of pathologic states such as reactive thrombocytosis[431] and essential thrombocytosis[432] and in myeloproliferative disorders that result in down-regulation of the MPL receptor,[433] all of which lead to elevated TPO levels in the face of thrombocytosis.

Thrombopoietin

TPO is synthesized as a 353-amino-acid precursor protein that undergoes subsequent removal of a 21-amino-acid sequence and posttranslational glycosylation to generate the mature 95-kDa molecule. Two functional domains have been identified: a receptor-binding domain that shares significant sequence homology to erythropoietin and a carbohydrate-rich carboxyl terminus that helps maintain protein stability.[434] The TPO receptor, c-Mpl, was discovered during study of the viral oncogene v-Mpl in the myeloproliferative (Mpl) leukemia virus.[435] Once the receptor was identified, the ligand (TPO) was rapidly isolated and cloned by several independent laboratories.[436–439] Binding of TPO to target cells results in receptor dimerization and activation of intracellular signaling pathways that include the Janus kinase (JAK)–signal transducers and activators of transcription (STAT) and Ras cascades.[440] The physiologic effects of TPO include increasing the size, ploidy, and number of marrow megakaryocytes and the elaboration of megakaryocyte-specific surface markers[441]; it does not appear involved in the release of platelets from mature megakaryocytes.[442] TPO also exerts trophic effects on erythroid and myeloid precursors in synergy with other growth factors, such as erythropoietin and stem cell factor.[439]

Recombinant Thrombopoietin

Development of rhTPO and PEG-rHuMGDF

Since TPO was first identified and cloned, two recombinant forms have been developed that have undergone extensive clinical testing: rhTPO and PEG-rHuMGDF.[443] The former, rhTPO (Pharmacia, Peapack, N.J.; formerly developed by Genentech, South San Francisco, Calif.), shares exact amino acid sequence homology with endogenous TPO; it is produced in mammalian cells and glycosylated. PEG-rHuMGDF (Amgen, Thousand Oaks, Calif.) is produced in *E. coli* and consists of the first 163 amino acids of endogenous TPO—the receptor-binding domain—that is conjugated to a 20-kDa polyethylene glycol moiety that confers prolonged circulatory half-life. Both formulations possess all of the biological properties of native TPO. Using a baboon model, research has shown that PEG-MGDF does not increase platelet secretory granule membrane protein P-selectin expression nor increase the binding of annexin V to platelet membranes.[444] In addition, direct exposure of platelets to various concentrations of PEG-rHuMGDF does not appear to hasten or retard development of the platelet storage defect as defined by a battery of in vitro tests of platelet structure and function.[445]

Clinical Studies of rhTPO and PEG-rHuMGDF

Both rhTPO and PEG-rHuMGDF are potent stimulators of platelet production in humans. Their clinical use in the treatment of oncology patients has recently been reviewed by Kuter and Begley.[443] It was observed that both forms of recombinant TPO have a half-life in excess of 40 hours, and increases in circulating platelet counts are generally not seen until at least 5 days after administration, with a peak effect normally present 10 to 12 days after administration. The time lag to effect is likely due to the fact that TPO exerts most of its effects on precursor cells and has little physiologic effect on mature megakaryocytes. In all clinical trials, TPO appeared well tolerated with minimal side effects reported from phase I dose-escalation studies.

Use of Recombinant TPO following Nonmyeloablative versus Myeloablative Chemotherapy

A significant difference in the degree of beneficial effects from the use of post-treatment recombinant TPO has been noted between nonmyeloablative and myeloablative chemotherapy regimens. Studies addressing the ability of PEG-rHuMGDF

to hasten hematologic recovery following nonmyeloablative chemotherapy for lung cancer, sarcomas, and gynecologic malignancies have generally shown modest benefits, including a reduction in the chemotherapy-related platelet count nadir, duration of thrombocytopenia, and number of platelet transfusions required.[446–448] Data from pediatric oncology trials in patients with recurrent or refractory solid tumors also suggest a promising role for recombinant TPO in reducing the severity of chemotherapy-associated thrombocytopenia.[449]

Myeloablative protocols in patients with leukemia or those undergoing hematopoietic progenitor cell (HPC) transplantation, however, have been disappointing. In aggregate, treatment with recombinant TPO in the setting of myeloablative chemotherapy in all studies failed to reduce the time to platelet recovery as marked by a platelet count of 20×10^9/L or greater or reduce the number of platelet transfusions needed prior to marrow reconstitution,[450–452] although a moderate increase in peak platelet counts and a reduction in the time to full platelet recovery were seen with both rhTPO and PEG-rHuMGDF. The reason for this is unclear, although a possible explanation is that the elevated levels of endogenous TPO commonly encountered with myeloablation may already have saturated available c-Mpl receptors.[443]

Adverse Effects of Neutralizing Antithrombopoietin Antibodies

In addition, the development of neutralizing antibodies against endogenous thrombopoietin has plagued clinical testing of thrombopoietic growth factors, in particular, PEG-rHuMGDF. These antibodies have caused severe thrombocytopenia in healthy volunteers and in oncology patients undergoing intensive chemotherapy.[453] This adverse effect has not been reported with rhTPO. One explanation offered for this observation is that PEG-rHuMGDF, which is truncated, nonglycosylated, and pegylated, is more immunogenic than the full-length glycosylated rhTPO form.[443] Additionally, rhTPO is generally administered intravenously while PEG-rHuMGDF is given as a subcutaneous injection. Because TPO is a potent mobilizer of dendritic cells, it has been postulated that the subcutaneous route of administration may also increase immunogenicity.

Treatment of HIV-Related Thrombocytopenia with Recombinant TPO

While the utility of recombinant TPO in hematologic malignancies appears unclear, its use in the setting of HIV-related thrombocytopenia appears more promising. PEG-rHuMGDF is effective in increasing platelet counts in chimpanzees with HIV-related thrombocytopenia.[444] In addition, case reports and small studies with HIV-infected patients likewise suggest improved thrombocytopenia following treatment with PEG-rHuMGDF.[443] These platelets, produced in response to PEG-rHuMGDF administration, demonstrate the expected responses to platelet agonists and ATP release in vivo, and their function is abrogated by aspirin.[454]

Mobilization for Platelet Apheresis Collection with Recombinant TPO

Likewise, recombinant TPO has shown potential benefits in mobilization of platelets for apheresis collection.[455] Studies with normal plateletpheresis donors have shown that PEG-rHuMGDF given as a single 2-μg/kg dose produced a doubling of the platelet count 9 to 14 days after administration. A single 3-μg/kg dose reliably produced a platelet count of 600×10^9/L. Single intravenous doses of PEG-rHuMGDF produced higher platelet elevations on day 5 after administration, whereas daily administration for 5 days produced a more prolonged thrombocytosis. Platelets collected by apheresis following PEG-rHuMGDF also were shown to have normal in vitro aggregation characteristics and produced expected increases in corrected count increments in thrombocytopenic recipients.

Use of Recombinant TPO in Autologous Marrow Transplantation

Finally, thrombopoietic growth factors have also been used in combination with other growth factors, such as FLT-3 ligand, to produce megakaryocytic progenitors ex vivo that can then be administered to autologous donors.[456–458] Other cytokines are under development that are designed to mimic the effects of TPO. A peptide agonist has been described that is a 14-amino-acid peptide with a high affinity for the thrombopoietin receptor.[459] This molecule was shown to be equipotent to the 332-amino-acid natural cytokines in cell-based assays. These small molecules that can activate receptors, replacing the need for large peptide ligands, may open the way for production of new types of hematopoietic stem cell growth factors.[460]

CONCLUSIONS

For the foreseeable future, clinicians will continue to rely on AD- and WB-Plts for the prophylaxis or treatment of bleeding in thrombocytopenic patients. Recently enacted AABB standards now stipulate mandatory bacterial detection for all platelet products, a move designed to address the relatively high incidence of bacterial contamination of platelets and the lower, but more serious, risk of septic transfusion reaction and sepsis-related deaths. With this additional testing has come renewed interest in extending the maximum shelf life of platelets from the current 5-day limit to 7 days, to help ease the economic and inventory burdens blood collection centers and transfusion facilities now face. It has also led many workers in the field to petition for accelerated development, validation, and adoption of pathogen reduction technologies, particularly in light of the ongoing emergence of new, potentially serious transfusion-transmitted diseases, such as West Nile virus.

Despite many advances in understanding of the basic biology of platelets, their translation into clinical practice has remained slow. Many basic questions remain unanswered, such as whether in vitro platelet tests can reliably predict in vivo function, how to determine a given patient's risk of bleeding, or what constitutes best platelet transfusion practice. The present pace of development of platelet substitutes likewise remains slow, despite some encouraging animal model data. This is also true for improvements in platelet storage methodologies. The use of recombinant thrombopoietin, despite its disappointing performance with myeloablative therapies, has shown demonstrable benefit in a variety of clinical scenarios. Clearly, a number of basic and clinical questions remain whose answers have the potential of dramatically affecting patient care and the ability to offer therapies now limited by intractable thrombocytopenia.

Chapter 24

Granulocytes

Thomas H. Price

INTRODUCTION

Infection associated with severe neutropenia continues to be a major limiting factor in the application of aggressive chemotherapeutic regimens and hematopoietic stem cell transplantation.[1–3] In the Trial to Reduce Alloimmunization to Platelets, 7% of patients undergoing induction therapy for acute myelocytic leukemia died of infection.[4] The spectrum of these therapy-related infections has shifted since the 1980s. Improved antibiotic regimens have reduced the incidence of refractory bacterial infection, and fungal infections have emerged as the principal infectious cause of mortality and morbidity.[5–7] Prophylactic use of fluconazole has reduced the incidence of disseminated *Candida* infection, and the leading cause of mortality has become infection with invasive molds such as *Aspergillus, Fusarium,* and *Zygomyces.*[5,8–10] The incidence of invasive *Aspergillus* infection in patients undergoing allogeneic bone marrow transplantation is approximately 15%, with a mortality rate of 30% to 80%.[5,7,11] *Fusarium* infection in these patients is associated with a 70% mortality rate.[9]

If these infections occur during periods of neutropenia, the provision of normally functioning neutrophils is a logical approach to the problem. The first reports of modern neutrophil transfusion therapy occurred in the mid-1960s, with large numbers of neutrophils obtained from donors with chronic myelocytic leukemia. The development of apheresis equipment shortly thereafter allowed the collection of transfusion doses of neutrophils from hematologically normal donors, and favorable clinical reports ushered in an era of enthusiasm for this therapeutic approach. A series of controlled trials followed that, on aggregate, indicated efficacy in terms of a survival advantage for patients given transfusions.

In spite of these results, granulocyte transfusion therapy all but disappeared from clinical use from about 1985 to 1995. This change in attitude occurred for several reasons. Improvement in antibiotic and general supportive care rendered refractory bacterial infection a less common clinical problem. Reports also surfaced of adverse effects of granulocyte transfusion, particularly adverse pulmonary reactions. Finally, and probably most important, the clinical results in most patients were, at best, marginal.

This unimpressive clinical efficacy had two probable causes. First, the dose of neutrophils supplied to patients with the best standard collection techniques, even in the mid-1990s ($20–30 \times 10^9$), was probably inadequate. Normal neutrophil production in an average-sized adult is approximately 60×10^9 cells per day in the uninfected state.[12] Although reliable quantitative information is lacking, the normal bone marrow is probably capable of increasing production severalfold in the presence of severe infection. Thus, the number of neutrophils routinely provided to patients undergoing neutrophil transfusion therapy was likely only about one tenth of the normal need. The second problem is that neutrophils rapidly undergo apoptosis after collection, a phenomenon that may be responsible for both the failure of the transfused cells to circulate and the short shelf life of these components.

Since the mid-1990s interest in granulocyte support therapy has been rekindled with the availability of granulocyte colony-stimulating factor (G-CSF), a cytokine that may be administered to granulocyte donors to increase the number of cells that can be collected.[3,13] G-CSF also inhibits neutrophil apoptosis, and this feature raises the possibility that in vitro and in vivo survival of these cells may be enhanced.

In this chapter, the features of traditional granulocyte transfusion are discussed first, including issues such as collection, storage, indications, evidence of efficacy, and adverse effects. This is followed by a discussion of the more recent experience using G-CSF to stimulate donors to obtain greatly increased numbers of cells for transfusion.

TRADITIONAL GRANULOCYTE TRANSFUSION THERAPY

Procurement of Granulocytes

Donor Selection

Granulocyte donors are selected from pools of community apheresis donors, or, perhaps more commonly, they are family members or friends of the patient. The ABO blood group is not important for granulocyte compatibility,[14] but donors should be ABO compatible with the patient because of the relatively large number of red blood cells contained in a typical granulocyte concentrate. Donors should be generally healthy and must meet the AABB and the United States Food and Drug Administration (FDA) standards for blood donation. There should be no contraindication to their receiving the institution's stimulation regimen (e.g., corticosteroids) for increasing the donor's blood neutrophil count. Infectious disease screening and testing must be the same as for any blood product, but modifications are often made in the timing of this testing to accommodate the need to transfuse the granulocytes as soon as possible after collection. In some centers, blood for infectious disease testing is drawn up to 24 hours before leukapheresis so that release of the cells will not be delayed.

CYTOMEGALOVIRUS (CMV) STATUS

If the patient is CMV seronegative, the donor should also be CMV seronegative, since most granulocyte recipients are in a patient population that requires CMV-safe components. The incidence of CMV transmission appears to be higher with granulocyte concentrates than with other cellular blood products because the latent virus resides in the leukocytes,[15,16] and the risk of transmission can be nearly eliminated by selecting seronegative donors. Needless to say, leukocyte reduction (leukoreduction), a technique available to render other blood components relatively CMV-safe, is not appropriate for granulocyte concentrates.

LEUKOCYTE COMPATIBILITY

If the patient is not alloimmunized, it is probably not necessary to select granulocyte donors on the basis of HLA or granulocyte typing or to perform leukocyte compatibility testing.[17] However, convincing evidence indicates that alloimmunized recipients who are transfused with incompatible leukocytes are more likely to experience adverse pulmonary reactions or febrile transfusion reactions.[18–22] In addition, the infused granulocytes will be rapidly cleared from the circulation and will be ineffective.[17,18,21,22–26] The difficulty is in knowing which patients are alloimmunized. Leukocyte antibodies detected in the laboratory do not necessarily correlate well with clinical evidence of alloimmunization, such as the ability of the transfused cells to circulate or to accumulate at sites of inflammation. In addition, reliable detection of clinically significant antibodies requires that a panel of sophisticated tests be performed,[19,24] tests that are not available in most institutions. In the absence of such results, a common approach is to attempt to gauge the likelihood of alloimmunization on the basis of information such as the patient's history of febrile transfusion reactions, response to random donor platelet transfusions, and results of a lymphocytotoxic antibody screen. If these results are normal, it is not likely that the patient is alloimmunized. Significant abnormalities in these parameters do not necessarily mean that the patient will have difficulty with granulocyte transfusions, but they do suggest that the physician proceed gingerly and also consider further clinical or laboratory evaluation.

Collection Procedure

Granulocytes are collected from donors by a leukapheresis procedure. Historically, two methods have been used: filtration and centrifugation. In the former, the donor's blood was passed over nylon wool filters to which the neutrophils adhered; the cells were subsequently eluted from the columns. Although large numbers of granulocytes could be collected by this technique, subsequent studies showed that the cells were functionally impaired.[27–29] In addition, the process itself activated complement and was associated with transfusion reactions in recipients and with occasional and sometimes serious adverse effects in donors.[30,31] This technique is no longer in use. For centrifugal leukapheresis, the cells are separated from other components by centrifugation. Numerous acceptable cell separators are on the market for this purpose. Usually, 7 to 10 L of the donor's blood are processed in a procedure that takes approximately 3 hours.

RED CELL SEDIMENTATION

It is necessary to add a red blood cell (RBC) sedimenting agent to the donor's blood to effect adequate separation of the granulocytes from the RBCs. Hydroxyethyl starch has traditionally been used for this purpose, and in modern cell separating machines this allows for 30% to 50% efficiency in granulocyte collection. Two preparations of hydroxyethyl starch are available for this purpose. Hetastarch, a high-molecular-weight compound, was the substance used originally, but it was shown to persist in the circulation for months. This persistence led to a concern for its safety, although long-term effects were not actually observed. The lower molecular weight version, pentastarch, was shown to have a much more rapid elimination time and appeared to function equivalently for the purposes of granulocyte collection.[32] Many collection centers switched to pentastarch as a result of these findings. More recent controlled studies showed, however, that collection efficiency is much greater when the high-molecular-weight preparation of hydroxyethyl starch is used.[33] Whichever agent is used, it must be infused continuously for as long as the collection proceeds in order to maintain the effect.

DONOR STIMULATION

In an effort to increase the number of granulocytes collected, donors are routinely stimulated with corticosteroids to mobilize cells from the marrow storage pool and to increase the circulating granulocyte count, thereby increasing the number of granulocytes that can be collected. Numerous stimulation regimens have been proposed, the most successful using up to 60 mg prednisone or 8 mg dexamethasone, which raises the donor's neutrophil count two- to threefold from baseline values.[34,35] Short-term administration of such doses of corticosteroids are well tolerated by most donors; persons with medical contraindications to such medications, such as active peptic ulcer disease or diabetes, should not be donors. Even higher donor granulocyte counts can be obtained by stimulation with G-CSF, a strategy discussed later in this chapter.

Cell Concentrate

Granulocyte concentrates are not licensed by the FDA and therefore have no defined regulatory specifications. AABB standards require that at least 75% of concentrates contain at least 10×10^9 granulocytes,[36] a value intended to serve as a benchmark for adequate collection technique but not to imply that 10×10^9 granulocytes is an adequate clinical dose. With the techniques discussed earlier, including adequate corticosteroid stimulation of the donor, mean yields of 20–30×10^9 granulocytes are typically achieved. Depending on the particular cell separator used, the granulocytes are suspended in 200 to 400 mL plasma and contain 10 to 30 mL red blood cells and 1–6×10^{11} platelets.

The functional capabilities of granulocytes obtained by these techniques have been the subject of many reports. In vitro and in vivo studies have shown repeatedly that cells collected by centrifugal apheresis are normal or nearly normal functionally, and the characteristics are not compromised by the use of hydroxyethyl starch or by stimulation of normal donors with corticosteroids.[27,37,38]

Storage of Neutrophils

After collection, granulocytes rapidly undergo apoptosis,[3,39,40] and this process greatly limits the ability to store the cells before transfusion. Although the hardier cell functions persist after a few days of liquid storage, the more sensitive ones, such as the ability to migrate, deteriorate more quickly.[41,42] In

vivo studies have shown that blood recovery and survival are adversely affected by as little as 24 hours of storage, and the ability of the transfused cells to localize to areas of inflammation is decreased as much as 75% after 8 to 24 hours of storage.[27,43] As a result of these observations, granulocytes should be administered as soon as possible after collection. In the event that this is not possible, the cells should be stored without agitation for no more than 24 hours.[36,44] The preponderance of evidence to date indicates that the cells should be maintained at room temperature for any period of storage.[41,45]

Transfusion of Granulocytes

Once the decision is made to initiate granulocyte support, the physician should strive to provide daily granulocyte transfusions until the patient's infection clears or until the patient's neutrophil count has returned to at least 500/μL. Data are insufficient to determine whether higher neutrophil counts would be more appropriate as stopping points for certain clinical conditions. Outside these parameters, it is generally not appropriate to stop and start transfusion support on the basis of the patient's daily clinical status.

Granulocyte concentrates usually contain 10 to 30 mL red blood cells, enough to cause a hemolytic transfusion reaction if the donor and patient are incompatible. Therefore, AABB standards require that an RBC crossmatch be performed before transfusion.[36]

Granulocyte preparations contain viable lymphocytes, and graft-versus-host disease has been reported after granulocyte transfusion.[46] Although this complication can easily be prevented by gamma-irradiation of the component, the decision to irradiate granulocyte concentrates routinely has been debated in the past. Those who opposed routine irradiation noted that graft-versus-host disease is an extremely rare complication, expressed concern that irradiation may compromise the integrity of the cells, and argued that, as with any other blood product, the decision to irradiate the cells should be based on clinical evaluation of the patient.[47] However, in regard to the last concern, most studies suggest that standard irradiation does not impair neutrophil function.[48–51] Since most patients receiving granulocyte transfusions are to some degree immunosuppressed and since transfusion-related graft-versus-host disease is almost uniformly fatal, it is recommended that granulocyte concentrates always be irradiated before transfusion.

Granulocytes should be administered through a standard blood administration set filter (170 μm) and infused over 1 to 2 hours. As mentioned above, the use of a leukoreduction filter is contraindicated. Administration of antipyretics or corticocosteroids is appropriate for patients who experience symptoms such as chills and fever; routine prophylaxis with these agents is not recommended except for patients who have previously experienced such symptoms.

CLINICAL EFFICACY OF NEUTROPHIL TRANSFUSION THERAPY

Neutropenia

Early Studies

The first reports of treating infected neutropenic patients with granulocyte transfusions occurred in the 1960s. In these studies, granulocytes were harvested from donors with chronic myelocytic leukemia by a manual leukapheresis technique whereby leukocyte-rich plasma was prepared from individual units of donor blood by sedimenting the red blood cells. Schwarzenberg and associates[52] treated 33 patients with various malignant diseases and reported that approximately half showed a favorable response. In several of the patients, the postinfusion rise in the patient's neutrophil count persisted, and the Philadelphia chromosome could be demonstrated in the patient's marrow cells, findings suggesting that a temporary graft had occurred. Morse and associates[53] used a similar technique and transfused 40 patients with leukopenia, most of whom had acute leukemia. Following 81 transfusions given to patients who were febrile before the transfusion, more than half of the patients were afebrile by 36 hours after the transfusion. Lowenthal and colleagues[54] collected granulocytes from normal donors and those with chronic myelocytic leukemia by continuous-flow centrifugation and treated 41 febrile patients with acute leukemia or aplastic anemia. Two thirds of the patients responded by defervescence. Response was more likely in those patients with proven or probable bacterial or fungal infection than in those with fever of unknown origin.

With the development of the automated cell separator, it became possible to collect large numbers of granulocytes from normal donors, and the use of donors with chronic myelocytic leukemia fell into disuse. A flurry of reports of granulocyte transfusion therapy in patients with neutropenia then followed. The aggregate experience was reviewed by Strauss[55] and is summarized in Table 24–1. In this review, patients were categorized by the infection for which the transfusions were begun and were counted only once. All patients with documented fungal infection were categorized as such, whether or not they fit into other categories. After these patients were excluded, all patients with sepsis were listed only in the sepsis section. The number of patients indicated in Table 24–1 represents the number of patients who could actually be evaluated for treatment efficacy, sometimes a much smaller number than actually treated. Therapy was considered successful if so indicated by the authors of the study. Although these results indicate the general experience with granulocyte transfusion therapy, care must be taken to not overinterpret the data. The number of patients often was small, and the studies represented were heterogeneous, with different inclusion criteria, granulocyte preparations, and criteria for success.

Controlled Trials

Included in the foregoing aggregate experience were seven controlled trials, reported between 1972 and 1982, designed

Table 24–1 Treatment of Neutropenic Patients with Granulocyte Transfusions

Infection	*N*	Success (%)
Bacterial sepsis	206	62
Sepsis, organism unspecified	39	46
Pneumonia, organism unspecified	11	64
Invasive fungal infection	77	36
Localized infection	47	83
Nonspecific fever	85	75

Adapted from Strauss RG. Granulocyte (neutrophil) transfusion. In McLeod BC, Price TH, Weinstein R (eds). Apheresis: Principles & Practice, 2nd ed. Bethesda, Md., AABB Press, 2003, pp 237–252.

to assess the efficacy of therapeutic granulocyte transfusion in adults.[56–62] In each of these studies, neutropenic patients with clinical evidence of infection who were treated with granulocyte transfusions were compared with a group of similar patients who received only conventional antibiotic therapy. All but two of the studies were randomized trials; in those that were not,[56,58] patients were assigned to the control group if no suitable granulocyte donor could be identified. When patient survival was compared, three of the studies showed a clear beneficial effect of transfusion. Higby and associates[57] treated patients with clinically evident infection with four daily transfusions and found that 15 of 17 treated patients and 5 of 19 control patients survived until day 20. Vogler and Winton[59] studied 30 patients with documented infection who had failed to respond to at least 72 hours of appropriate antibiotic therapy; survival to 22 days was 59% in the transfused group and 31% in the control group. Herzig and associates[61] treated 27 patients with documented gram-negative septicemia; 75% (12 of 16) of the treated group survived compared with 36% (5 of 14) of the control group. When these results were further analyzed, the survival advantage was entirely in the subset of patients who did not recover bone marrow function.

Two of the controlled trials showed no statistically significant overall beneficial effect of transfusion, but subset analysis suggested efficacy in certain groups. In the study of Graw and colleagues[56] of patients with documented gram-negative septicemia, overall survival was not improved in the treatment group, but survival was improved for those who received at least four transfusions. In the other study with partial benefit, that of Alavi and colleagues,[60] no advantage of granulocyte transfusion was apparent for the overall patient population; however, in the subgroup with persistent bone marrow failure, 75% of the transfused patients survived compared with 20% of the controls.

In two of the controlled studies, no benefit to transfusion was identified. Fortuny and associates[58] treated 58 febrile episodes in 39 patients with acute nonlymphocytic leukemia. Survival of the episode was 78% in the transfused group versus 80% in the control group. Winston and colleagues[62] studied 95 neutropenic patients with documented infections; 63% (30 of 48) of the transfused patients and 72% (34 of 47) of the controls survived the infection.

In trying to understand the somewhat disparate results of these controlled trials, it is useful to keep in mind that the number of patients involved in many of the studies was relatively small, and the study designs and evaluation parameters were different. Whether efficacy was demonstrated may have been primarily influenced by the survival of the control group. In those trials in which the control group did well, it would be difficult to demonstrate that additional benefit was provided by transfusion therapy, even if the therapy itself was generally useful. As discussed later, subsequent analysis of these studies also suggested that the positive studies generally were those in which larger numbers of functional neutrophils were provided, as well as those in which some attempt was made to take leukocyte compatibility into account.[63,64] Moreover, by modern standards, only one of the controlled studies[59] provided adequate numbers of functional neutrophils as a transfusion dose. In four of the studies, cells were collected by filtration leukapheresis, a technique now known to produce damaged cells.

Despite the foregoing caveats, the aggregate message from the controlled therapeutic trials is that, in the proper clinical circumstances, granulocyte transfusion therapy is likely beneficial, a conclusion that is bolstered by meta-analysis.[64] The current standard indications for granulocyte transfusion therapy were derived from these controlled trials—namely, that patients are severely neutropenic, that they have a documented infection, and that the infection has not responded to appropriate antimicrobial therapy. These clinical criteria, although developed over 20 years ago, still seem eminently reasonable.

Fungal Infection

No systematic studies have been conducted to evaluate the role of granulocyte transfusion therapy in the treatment of documented fungal infection. Experimental studies in dogs suggested that transfused neutrophils may be effective. Ruthe and associates[65] used a dog *Candida* sepsis model to show that the extent of infection could be reduced by granulocyte transfusions. Chow and coworkers[66] developed a *Candida* meningitis model in dogs and showed that transfused neutrophils were capable of migrating into the cerebrospinal space and increasing survival.

Reports of granulocyte transfusions in patients with fungal infection have mostly consisted of case reports.[67,68] Bhatia and associates[69] conducted a retrospective study of granulocyte transfusion therapy in 87 patients who were undergoing bone marrow transplantation and who had various systemic fungal infections. No beneficial effect of transfusion was seen. It is difficult to draw conclusive answers from this study for several reasons: it was a retrospective study in which patient entry was controlled only by the patient's physician; the control group and the treatment group were not comparable; the dose of granulocytes delivered was largely unknown and was probably inadequate because the granulocyte donors were not stimulated with corticosteroids; and the collection parameters were not optimal. Clinical trials are obviously needed to address the issue of efficacy in fungal infection. In the meantime, it is probably reasonable to provide granulocytes to patients with a serious systemic fungal infection that is refractory to conventional therapy.

Prophylactic Transfusion

If granulocytes are effective in treating an established infection, it would seem logical that they could even be more effective in preventing infection in neutropenic patients. Numerous controlled trials of prophylactic granulocyte support were reported from 1977 to 1984 and were summarized by Strauss.[70] As with the trials of therapeutic transfusion, positive effects were limited to those in which larger doses of granulocytes were provided. The effects were modest, however, and some studies reported a high rate of adverse effects.[20,71] Cost-effectiveness analysis contemporary to these studies showed that provision of prophylactic support was also very expensive.[72]

Neonatal Sepsis

Bacterial sepsis occurs in 1 to 10 per 1000 neonates and is associated with an average mortality of approximately 20%.[70] A contributing factor to this high mortality is relative dysfunction of neonatal neutrophils, cells that have been shown to exhibit quantitative abnormalities in chemotaxis, adhesion, and oxidative metabolism.[70] As a result, neonates with sepsis whose blood neutrophil counts are less than 3000/μL and who have diminished marrow neutrophil stores have a

high mortality in spite of antibiotic treatment.[73] The efficacy of granulocyte transfusion therapy in the setting of neonatal sepsis was evaluated in six controlled trials[74–79] and reviewed by Strauss.[70] In four of the six studies, a survival benefit was identified in patients who received granulocyte transfusions, although subsequent meta-analysis concluded that the studies were so heterogeneous that no definite conclusion could be reached about efficacy.[64]

In the study of Laurenti and associates,[74] which was controlled but not randomized, 20 neonates with sepsis received 2 to 15 granulocyte transfusions, and these patients were compared with 18 similar patients who did not receive transfusions. Survival was 90% in the transfused group and 28% in the control group. The granulocytes were collected by filtration leukapheresis and, for half of the transfused patients, were stored for up to 2 days before transfusion; these features would suggest that the cells were probably nonfunctional. Christensen and colleagues[75] randomized 16 neonates with bacterial infection and depleted marrow neutrophil storage pools. All the transfused patients (7 of 7) and 11% (1 of 9) of the controls survived. Cairo and associates[76] randomized 23 newborns with clinical sepsis; those who received transfusions were transfused every 12 hours for a total of 5 transfusions. Survival of the transfused group (13 of 13) was significantly higher than that of the control group (6 of 10). When analysis was limited to those patients with positive blood cultures, there was still a survival advantage to those who received transfusions (100% vs 57%), but the difference was no longer statistically significant.

In a subsequent randomized study, Cairo and associates compared granulocyte transfusion therapy with intravenous immune globulin treatment in the same clinical population.[77] Again, all the neonates who received transfusions (21 of 21) survived, whereas only 64% (9 of 14) of those treated with immune globulin survived. In the remaining two studies,[78,79] no survival advantage was seen with transfusion, but in both studies the granulocytes were prepared from units of whole blood, rather than by leukapheresis, and this makes the viability of the cells suspect.

In summary, the role of granulocyte transfusion therapy in neonatal sepsis is not clear. As a practical approach, it is probably reasonable to recommend that in institutions experiencing high mortality in this clinical situation, granulocyte support be considered in neonates with sepsis who have blood neutrophil counts less than 3000/μL with evidence that the marrow storage pool is depleted.

Granulocyte Function Disorders

Patients with severe neutrophil dysfunction, who may have normal or even elevated blood neutrophil counts, may also benefit from granulocyte transfusion therapy. Some investigators have reported, usually as single case studies, apparent clinical success in treatment of antibiotic-resistant bacterial or fungal infection in patients with disorders such as chronic granulomatous disease and leukocyte adhesion deficiency.[80–84] Although few patients have these disorders and controlled trials have not been performed, efficacy of such therapy can be very convincing with an individual patient who has recurring infections. At the Puget Sound Blood Center in Seattle, the author treated a patient with leukocyte adhesion deficiency (originally described by Bowen and associates[84]) over the course of 15 to 20 years. He was repeatedly unable to clear bacterial infections until he received a course of granulocyte transfusion therapy. The indications for transfusion in patients with neutrophil function disorders are not firmly established. The physician should probably be conservative, however, because these patients ordinarily have immune systems that are otherwise functional, and alloimmunization can be a significant problem.[19]

Adverse Effects

Fever and chills are fairly commonly seen after the administration of granulocytes. Precise figures are not available, but the incidence depends on the likelihood of alloimmunization.[19] As an approximation, nonimmunized patients can expect to experience mild to moderate fever or chills with about 10% of transfusions. Routine premedication is not necessary, but for those patients experiencing reactions, premedication with acetaminophen or corticosteroids often prevents recurrences. Moderate to severe pulmonary reactions can occur in these patients, but true transfusion reactions are often difficult to distinguish from other conditions such as fluid overload or underlying pulmonary disease.[85] Wright and associates[86] reported a high incidence of severe pulmonary reactions in patients receiving both granulocyte transfusions and amphotericin B, a finding that several investigators have failed to confirm.[22,85,87,88] Nevertheless, it remains common practice to space the administration of amphotericin from that of granulocytes by several hours.

In addition to affecting the ability to provide effective granulocyte support, alloimmunization may be a complication of such support. The incidence likely depends on the integrity of the patient's immune system as well as the tests used to detect antibody. Stroncek and colleagues[19] reported that approximately 75% of patients with chronic granulomatous disease who receive repeated courses of granulocyte support will develop clinically significant antibodies. Other studies have detected leukocyte antibodies after granulocyte transfusion in 40% to 80% of patients with acute leukemia or various marrow failure states.[89,90] In the study of Price and colleagues[91] baseline incidence of alloimmunization, as measured by the presence of HLA antibodies, was approximately 10% in patients undergoing hematopoietic stem cell transplantation. After a course of granulocyte transfusions, another 25% developed HLA antibodies, but the presence of these antibodies appeared to have no effect on the posttransfusion neutrophil increments observed or on the incidence of transfusion reactions. Adkins and associates, on the other hand, reported that patients with preexisting lymphocytotoxic antibodies eventually experienced reduced neutrophil increments after a series of prophylactic neutrophil transfusions.[92]

As previously discussed, graft-versus-host disease, a highly fatal but unusual complication of granulocyte transfusion therapy, can be prevented by gamma-irradiation (2500 cGy) of the concentrate.

GRANULOCYTE TRANSFUSION THERAPY USING DONORS STIMULATED WITH G-CSF

Granulocyte Dose

An important reason for the unimpressive efficacy of traditional granulocyte transfusion therapy is the inadequacy of the cell dose usually provided. Evidence of the importance of dose comes from several quarters. First, in the early,

uncontrolled trials of granulocyte transfusion therapy, in which large doses of cells could be obtained from donors with marked leukocytosis, clinical responses were reported to be associated with the dose delivered. Morse and associates[53] observed that the increase in the patient's neutrophil count was directly related to the dose of cells provided and was detectable only if the dose exceeded $10^{10}/m^2$. The clinical response, as defined by defervescence, was also proportional to the dose, the fraction of patients responding ranging from 30% to 100% with mean doses of $2.6 \times 10^{10}/m^2$ and $15.6 \times 10^{10}/m^2$, respectively. Lowenthal and colleagues[54] reported that patients with clinical responses received, on average, four times as many cells as patients without responses. Second, retrospective analysis of the controlled trials of therapeutic granulocyte transfusion therapy suggested that higher doses of cells were provided in the studies that showed efficacy.[63,64] Third, the experience with the provision of granulocytes to neonates, in whom the relative dose is much higher because of the size of these patients, suggests that efficacy is determined by dose. Finally, studies in animals indicated the importance of dose. Appelbaum and associates[93] examined the clinical effect of granulocyte support in dogs with *Pseudomonas* sepsis and showed that dogs receiving 10^8 cells/kg did not survive the infection, whereas 100% (5 of 5) survived when they were given 2×10^8 cells/kg. Epstein and Chow[94] provided granulocytes to dogs with *Candida albicans* meningitis and showed a direct relationship between the dose of cells administered, the blood granulocyte increments, and the number of granulocytes migrating to the cerebrospinal fluid.

Actions of G-CSF

With the availability of recombinant G-CSF, the possibility of greatly increasing the number of granulocytes for collection and thus for transfusion raised the hope that the efficacy of granulocyte transfusion therapy could be improved.[3,13] When administered to normal subjects, G-CSF causes a rapid dose-dependent increase in the neutrophil count, beginning within 2 hours and peaking at approximately 12 hours.[95] This phenomenon is the result of the rapid release of neutrophils from the marrow storage pool into the blood. When given daily, G-CSF also stimulates the proliferation of granulocyte precursors and accelerates the transit time of the developing cells through the maturation pool into the blood.[96] G-CSF also affects neutrophil function. It increases phagocytosis as well as bactericidal and fungicidal activity.[39,97,98] It primes neutrophils and enhances their metabolic responses to second agonists.[39] It affects the expression of cell surface proteins such as CD64, CD35, CD14, and CD11/18,[38,98,99] proteins that are important in cell adhesion processes. G-CSF also inhibits neutrophil apoptosis,[39,101] a finding that may explain, in part, the prolonged blood survival of neutrophils from subjects given the drug.[96]

Stimulation of Donors with G-CSF

The use of G-CSF to stimulate normal granulocyte donors has been reported by numerous investigators (Table 24–2). In most of these studies, G-CSF was administered repeatedly to donors who were family members or friends of the patient who received the transfusions, although in the study of Price and associates,[91] the donors were community apheresis donors who were recruited to donate for patients whom they did not know. The dose of G-CSF in these studies ranged from 5 to 10 μg/kg, and it resulted in granulocyte concentrates containing an average of 40 to 60×10^9 cells. Leitman and associates[102] and Price and colleagues[91] achieved substantially higher average yields (80×10^9 cells) by administering both G-CSF and dexamethasone (8 mg) to normal subjects. Liles and coworkers[103] determined that the addition of corticosteroids resulted in higher donor blood neutrophil counts, irrespective of the dose of G-CSF, and the maximum neutrophil counts occurred approximately 12 hours after stimulation. Administration of G-CSF, with or without corticosteroids, is well tolerated by donors.[104,105] Most donors experience mild to moderate bone aching, headache, or insomnia. In one study, 98% of donors were willing to undergo future G-CSF stimulation.[91]

Because G-CSF has been shown to inhibit neutrophil apoptosis,[39,101] this cytokine may be useful in lengthening the acceptable storage time for neutrophils and thereby improving the logistics of granulocyte therapy programs. Whether this will turn out to be true awaits further studies.

Hematologic Effect in Recipients

In marked contrast to the situation in traditional granulocyte transfusion therapy, the postinfusion neutrophil increments seen in patients receiving these large doses of cells are quite substantial. Hester and associates[106] reported a mean posttransfusion neutrophil increment of $0.6 \times 10^3/\mu L$ after infusion of 40×10^9 granulocytes, and the value remained higher than the baseline value for 24 hours. In the study of Adkins and colleagues,[107] patients received a mean granulocyte dose

Table 24–2 **Granulocyte Colony-Stimulating Factor (G-CSF)–Stimulated Granulocyte Collections**

	N	G-CSF	Donor PMN ($10^3/\mu L$)	PMN Yield (10^9)
Caspar et al[124]	22	300 μg	20	44
Hester et al[106]	124	5 μg/kg/day	24–36	41
Bensinger et al[125]	58	5 μg/kg/day	15–40	42
Jendiroba et al[126]	221	5 μg/kg/day	—	42
	179	5 μg/kg/day or every other day	—	46
Adkins et al[107]	29	5 μg/kg/day	20–30	51
Grigg et al[116]	55	10 μg/kg/day	—	59

Price et al[91]	175	600 μg Dexa 8 mg	31	82

Dexa, dexamethasone; PMN, polymorphonuclear leukocytes.

of 51×10^9 and exhibited a mean post-transfusion neutrophil increment of $1 \times 10^3/\mu L$, a value that was maintained for 1 to 1.5 days. With even higher cell doses (mean 82×10^9), as reported Price and coworkers,[91] post-transfusion neutrophil increments were $2.6 \times 10^3/\mu L$, with an average next morning count of $2.6 \times 10^3/\mu L$. It thus appears that donors stimulated with G-CSF and corticosteroids are able to provide enough granulocytes to sustain a normal or near-normal blood neutrophil count in the most severely neutropenic patients. Strong evidence indicates that these granulocytes are also capable of migrating to extravascular sites. Dale and associates[108] showed that neutrophils collected from G-CSF–stimulated normal donors were able to accumulate in skin chambers. Adkins and colleagues[109] reported that ^{111}In-labeled granulocytes obtained from G-CSF–stimulated donors were able to localize to areas of infection in neutropenic recipients. Price and coworkers[91] measured buccal neutrophil accumulation in neutropenic granulocyte recipients and demonstrated the ability of the transfused cells to migrate to the extravascular compartment.

Recipient Adverse Effects

Transfusion of granulocytes obtained from G-CSF–stimulated donors has generally been well tolerated by recipients. In the study of Adkins and associates,[107] 29 HLA-matched transfusions were administered to 10 patients. After one of the transfusions, the patient experienced dyspnea, cough, and the sensation of a large tongue, all of which disappeared after treatment with antihistamines. No febrile or other respiratory reactions were seen. Hester and associates[106] reported adverse pulmonary reactions in approximately 5% of transfusions, reactions characterized by varying degrees of dyspnea, hypoxia, and changes on the chest radiograph. In the study of Price and associates,[91] chills and fever were seen in only about 10% of patients. These reactions were mild to moderate and were preventable in subsequent transfusions by treatment with antipyretics or corticosteroids. No changes were seen in blood oxygen saturation measured before and after the transfusions. Although this experience is encouraging, the likelihood of alloimmunization is low in the groups of patients studied to date. Similar results may not occur with transfusion of multitransfused patients with intact immune systems, such as those with neutrophil function disorders.

Clinical Efficacy

The evidence that providing large numbers of granulocytes from G-CSF–stimulated donors is clinically efficacious is limited to case reports[110–114] and small uncontrolled series.[91,106,115,116] Hester and associates[106] transfused 15 patients with fungal infection and reported that 60% responded. Eighty-three percent of patients (15 of 18) with established bacterial or fungal infection recovered in the series reported by Taylor and colleagues.[115] Results were more discouraging in the study of Grigg and associates,[116] in which 3 of 3 patients with bacterial infection survived, but 5 of 5 with fungal infection died. Kerr and colleagues prophylactically transfused G-CSF/dexamethasone–stimulated granulocytes in nine allogeneic stem cell transplant patients considered to be at high risk for the development of invasive fungal infection.[117] Six of the patients had previous invasive *Aspergillus* infection, and two had prolonged neutropenia. Results were compared to that of 18 control patients. Patients receiving prophylactic granulocytes were significantly less likely to develop fever (25% vs 100%) and the mean number of days with fever was less (2.5 vs 7.1). Of the six patients in whom it possible to judge response radiographically, four improved and two worsened. In a prospective uncontrolled study, Lee and associates[118] treated 32 patients with neutropenia-related infection with a mean of 3.8 G-CSF–stimulated granulocyte transfusions. Clinical responses were reported in 80%, 67%, and 50% of fungal, gram-negative bacterial, and gram-positive bacterial infections, respectively. The fate of infused Tc99m-labeled granulocytes was measured in two responders and two nonresponders; the cells localized to the area of infection in both responders but failed to so localize in the nonresponders, suggesting that efficacy depends on the cells' ability to home to the site of infection.

Peters and coworkers[119] administered granulocyte transfusions to 30 children with documented infection. Fifty-eight percent of the granulocyte concentrates were from G-CSF–stimulated donors. Since the patients were children, the average dose of granulocytes per kilogram was relatively high. In this uncontrolled series, recovery from bacterial and fungal infection was 82% and 54%, respectively. Rutella and colleagues[120] treated 20 patients with a variety of bacterial and fungal infections with G-CSF–stimulated granulocytes. Overall, 50% of patients responded, response rates being equivalent for those with bacterial or fungal infection. However, no patient with a localized invasive fungal infection responded. Price and associates[91] treated 19 bone marrow transplant recipients with a variety of bacterial and fungal infections. Infection resolved in 8 of 11 patients with invasive bacterial infections or candidemia; none of the eight patients with invasive mold infection, however, survived 30 days to document clearance of infection. More recently, Nichols and associates reported on a phase II multicenter feasibility trial in which 39 patients with neutropenia and documented infection were treated with daily granulocyte transfusions from G-CSF–stimulated donors.[121] A microbial response was observed in 38%, 60%, and 40% of patients with invasive mold infection, tissue bacterial infection, and bacteremia/fungemia, respectively.

In a retrospective case-controlled study, Hubel and colleagues examined the effect of G-CSF–stimulated granulocyte transfusion therapy on the course of infection and on overall survival in 74 patients undergoing bone marrow transplantation.[122] These results were compared to those of a matched cohort of 74 patients who received antimicrobial therapy alone. The fraction of patients with progressive infection was actually greater in the transfused group (57% vs 39%), although the difference was not statistically significant for patients with fungal infection. No differences were seen in the overall survival rate. These negative results must be interpreted with caution. This study was not a prospective randomized study, the "controls" were partly historical, and the patients selected to receive granulocyte transfusions were likely to have had more severe illness. Regardless, these data do not provide clear evidence that granulocyte transfusions are clinically effective.

In another case-controled study, Safdar and associates[123] analyzed 491 patients with candidemia. Twenty-nine of these patients received granulocyte transfusions; 429 did not. Short-term survival was comparable (48% in the transfused group, 45% in the control group) in spite of the fact that a number of risk factors for higher mortality were more common in the patients receiving granulocytes (e.g., longer duration of neutropenia, higher incidence of breakthrough invasive fungal infection). The authors interpreted these findings to be supportive of the notion that the transfusions were effective.

Of note, many of these trials were conducted prior to the availability of antifungal agents that are more effective and less toxic than conventional amphotericin B, including the third-generation triazole voriconazole. It is possible that the administration of more effective therapy would allow the incremental benefit of granulocyte therapy to be more clearly demonstrated, but this hypothesis remains to be proved.

CONCLUSION

Many studies have shown that G-CSF (with or without corticosteroid) stimulation of normal donors causes marked neutrophilia and permits the collection of large numbers of functional granulocytes for transfusion. G-CSF is well tolerated by the donors, although mild side effects are fairly common, and more serious adverse events can occur. The transfusion of these large numbers of granulocytes usually results in a substantial increase in the patient's blood neutrophil count. Transfusion reactions can occur and are usually mild, although serious pulmonary reactions occur in approximately 5% of patients, an incidence that may depend on the frequency of alloimmunization. These reactions do not seem to be more common or severe than those seen with the administration of granulocytes obtained without donor G-CSF stimulation. The remaining critical question is whether the transfusion of large doses of granulocytes is clinically effective in eradication of infection or in prolonging patient survival. Evidence for efficacy to date is only anecdotal or based on small, uncontrolled series. Some of these series have suggested efficacy, impressing some clinicians that the therapy is useful; others have shown no effect. The current situation is one of clinical equipoise. It is not clear whether this rather expensive therapy would be advantageous, disadvantageous, or neutral, given that clinical efficacy is uncertain and there are known possible adverse effects for both donor and patient. Clarification will only be possible by means of a large-scale, randomized, controlled clinical efficacy trial. Such a trial is in its final planning stages within the National Heart, Lung, and Blood Institute's Transfusion Medicine/Hemostasis Network and may be under way by the time of publication of this text.

Chapter 25

Coagulation Factor Preparations

James C. Zimring • Alexander Duncan

This chapter introduces the different types of coagulation factor concentrates that are available, the advantages and disadvantages of utilizing different products, and the indications for their use. Detailed information on dosing and administration of a given product should be obtained from the published guidelines for that product.

REPLACEMENT THERAPY FOR COAGULATION FACTOR DEFICIENCIES

Since the initial descriptions of hemophilia and von Willebrand disease, it has been appreciated that the coagulation system is made up of discrete factors, the absence of which can result in life-threatening bleeding. Early attempts to replace such factors consisted of transfusing plasma. However, the low concentrations of coagulation factors in normal plasma are a limiting factor to this approach, since there is a maximal rate of plasma infusion and total volume that a patient can tolerate. Treatment of specific factor deficiencies was improved with the introduction of relatively crude fractions of plasma that effectively concentrated the desired factors (i.e., cryoprecipitate). However, such products contain only certain factors (predominantly vWF, VIII, XIII, and fibrinogen). In addition, multiple pooled units of cryoprecipitate carry the risk of transmitting infectious disease from donors.[1] Further advances in factor purification provided concentrates of factors VIII and IX for the treatment of hemophilia A and hemophilia B, respectively. Modern concentrates are now subjected to pathogen inactivation techniques, which minimizes but does not eliminate the risk of infection.[2,3] More recently, recombinant DNA technology has allowed the expression of human coagulation factors in vitro, which essentially eliminates the risk of transmitting human pathogens that could co-purify from donor plasma. However, since some products are stabilized with human albumin, it has been suggested that a risk of transmission of selected pathogens, such as parvovirus B19 and prions remains a possibility.[2] The current move to albumin free stabilizers may address this issue.[4–6]

PURIFIED VERSUS RECOMBINANT COAGULATION FACTORS

Prior to the advent of recombinant DNA technology, the only available source of human coagulation factors was purification from plasma donors. The advantage to this approach is that the factors are derived from their natural biological source, which results in a biochemically authentic factor. However, there are a number of distinct disadvantages to purifying coagulation factor concentrates from human donors. There is always the concern of transmitting infectious agents from the donor into the recipient. Indeed, before HIV was identified as the causative agent of AIDS, a large number of hemophilia patients were infected from HIV-tainted purified factor VIII. Current purified human factor VIII is obtained only from donors who screen negative for the known transmissible pathogens. However, this will not protect factor VIII recipients from unidentified emerging pathogens that may enter the blood supply in the future. For this reason, there are ongoing efforts to perfect sterilization techniques that would potentially inactivate all pathogens. Since coagulation factors are proteins, these techniques focus on methodologies that do not damage proteins, such as cross-linking of nucleic acids (DNA or RNA) or disrupting membranes of lipid-enveloped pathogens. However, such techniques will not inactivate prions, since, like coagulation factors, prions are also proteins. Thus, transmission of spongiform encephalopathies remains a concern.[7,8]

The advent of recombinant DNA technology has allowed the cloning of cDNAs and the ectopic expression of human proteins in cell culture. This process allows for the expression and purification of large quantities of the protein products of human genetic sequences and essentially eliminates the risk of pathogen transmission from human donors. A residual risk of infection from pathogens of animal origin remains, since animal serum typically is required to culture the cell lines producing the factors. In addition, albumin of human or animal origin has been required to stabilize recombinant factors. These additives provide a potential residual source for introducing infectious material. However, recent advances have circumvented these technical limitations. For example, in 2003 the U.S. Food and Drug Administration (FDA) approved a recombinant factor VIII product expressed in Chinese hamster ovary cells, which has never come into contact with products from human or animals. Although it is still theoretically possible that undetected pathogens harbored in the cell lines themselves may infect human recipients, recombinant factors expressed in serum-free systems without albumin additives are as close to being pathogen free as is possible in culture-based systems.

Despite the above attributes, there are several disadvantages to utilizing recombinant factors. These products are typically expressed from nonhuman cell lines, such as Chinese hamster ovary cells. Thus, in patients who have hypersensitivity to mice or hamsters, allergic side effects can theoretically be observed. Although it is rare to observe allergic reactions to recombinant products,[9] anaphylaxis after administration of recombinant factor VIII has been

reported, but it is unclear whether the reaction was due to hypersensitivity to contaminants in the factor VIII preparation.[10] Thus, allergic reactions remain a possibility, and known hypersensitivity to animals from which the expressing cell lines are derived is considered a contraindication to utilizing factors expressed in such cell lines.

An additional issue is that human gene products expressed in cell lines may have different post-translational modifications (glycosylation, phosphorylation, etc.) from the naturally occurring material. This can introduce neo-epitopes that may constitute a foreign entity to the host immune system. Thus, it is possible that recipients of recombinant factors may develop antibody inhibitors against foreign "non-natural" epitopes on the recombinant factor. Although the above concerns may cause problems in the case of certain recombinant factors, current preparations of recombinant factor VIII do not show increased frequency of inhibitor induction in previously untreated patients.[11] However, it has been reported that the change from one factor VIII preparation to another may increase risk of anti–factor VIII antibodies, perhaps as a result of neoantigen exposure.[12]

HUMAN VERSUS ANIMAL COAGULATION FACTORS

The sequences of coagulation factors are sufficiently conserved in nonhuman mammals that purified coagulation factors from nonhuman sources can be used in some settings to treat factor deficiency states. There is a slightly decreased risk of viral transmission of pathogens, since most viruses are species specific. However, some cases of viral transmission may occur,[13] and numerous porcine pathogens may potentially contaminate tissues or products of porcine origin.[14] In addition, there is a theoretical concern that introduction of undetected animal viruses into humans may result in novel recombination with human viruses, which could lead to the generation of new human infectious entities. The greatest utility for coagulation factors of nonhuman origin has been limited cross-reactivity with antibody inhibitors against human coagulation factors. In particular, porcine factor VIII has been used to circumvent antibody inhibitors against human factor VIII (see below).

FACTORS USED TO TREAT BLEEDING DIATHESES

Treatment of Congenital Hemophilia A

Replacement therapy with factor VIII has long been the treatment for patients with hemophilia A. A wide variety of human factor VIII replacement products are available including both recombinant factor VIII and factor VIII products purified from human plasma. In addition, modified factor VIII and porcine factor VIII can be used in the context of anti–factor VIII antibody inhibitors (see below). Currently, recombinant products are the treatment of choice because they confer the lowest risk of infectious disease transmission and may reduce the risk of inhibitor development.

Recombinant Factor VIII Products

Recombinant factor VIII was first approved by the FDA for human use in 1992. Although these early products were produced from cell lines, they required that the cells be cultured in media containing animal serum and that the products be stabilized with albumin of animal origin. Advances in cell culture technology have resulted in FDA approval of recombinant factor VIII expressed in a culture system to which no animal serum or products are added.

Recombinant factors provide the lowest risk of transmission of infectious agents, especially factors expressed in culture systems that do not require the addition of serum. As mentioned above, hypersensitivity to mice or hamsters can be a contraindication, because it may lead to allergic reactions to co-purifying proteins or monoclonal antibodies. Although isolated incidents of allergic reactions after recombinant factor VIII administration have been reported,[10] sensitivity to mouse or hamster contaminants has not been observed.[15] Overall, recombinant factor VIII products are well tolerated and highly efficacious in the treatment of factor VIII deficiency.

It is worth noting that unlike partially purified human factor VIII (e.g., Humate-P), in which case von Willebrand factor (vWF) co-purifies with factor VIII, recombinant factor VIII contains no vWF. Accordingly, while partially purified factor VIII can be used to treat von Willebrand disease (vWD) in addition to factor VIII deficiency, recombinant factor VIII is not a viable treatment for vWD.

Purified Factor VIII Products

Prior to the advent of recombinant factor VIII, patients with hemophilia A were treated with purified factor VIII isolated from plasma of human donors. Initially, procedures for producing partially purified plasma fractions highly enriched for factor VIII were utilized. To minimize the risk of infectious disease transmission, such products are subjected to treatments that typically inactivate pathogens, such as pasteurization or chemical inactivation with solvent and detergents. In addition to factor VIII, these enriched products also have high amounts of vWF that co-purifies with factor VIII. Thus, these products are also useful in treating certain forms of vWD (see below).

Further progress in purifying factor VIII was made with implementation of affinity purification using monoclonal antibodies to human factor VIII. Isolation of factor VIII by this procedure results in a highly purified product. Only a small quantity of vWF co-purifies with factor VIII by this approach. Accordingly, this product is not useful for the treatment of vWD. Purification and pathogen inactivation limit the chance of transmitting pathogens from the donor. In addition, small amounts of monoclonal antibody may be present in the final factor VIII preparation, which can result in allergic reactions in patients who have hypersensitivity to mice or hamsters.

Although rare, the type 2N vWD (Normandy) consists of a mutation in vWF that no longer stabilizes factor VIII.[16] In this case, the half-life of factor VIII decreases to the point that only very low levels of circulating factor VIII persist. Thus, it is possible for a patient with type 2N vWD to be misdiagnosed as having hemophilia A, since factor VIII levels are very low and vWF antigen is normal. In such a case, partially purified factor VIII (e.g., Humate-P) will correct the defect due to the co-purification of vWF. However, highly purified or recombinant factor VIII will have no efficacy in this setting, since vWF is largely removed during the purification process.

Cryoprecipitate

Cryoprecipitate contains a concentrate of factors VIII, vWF, XIII, and fibrinogen. In the United States, current use of cryoprecipitate is almost exclusively limited to the replacement of fibrinogen in hypofibrinogenemic patients. However, prior to the advent of purified factor VIII, cryoprecipitate was the mainstay of treatment for hemophilia A. In settings in which recombinant and purified factor VIII are not available, cryoprecipitate still is used to treat hemophilia A. Likewise, cryoprecipitate also has vWF and can be used to treat vWD, if vWF-containing factor VIII products are not available. However, unlike the partially purified factor VIII preparations, cryoprecipitate is not routinely subjected to pathogen inactivation treatments. Depending on the donor populations and screening procedures, the lifetime risk of contracting HIV infection from treatment of hemophilia with monthly infusions of cryoprecipitate has been estimated from 2% to 40%.[1] Accordingly, use of cryoprecipitate for treatment of hemophilia A and vWD should be limited to circumstances in which no other factor VIII product is available.

Treatment of Anti–Factor VIII Antibody Inhibitors

Antibodies against factor VIII can result in rapid clearance or functional inactivation of factor VIII.[17] Anti–factor VIII antibodies are most commonly seen in hemophilia A patients who mount a humoral immune response against replacement factor VIII. Since the factor VIII gene is either absent or altered in hemophilia A patients, wild-type factor VIII is not recognized as self. Thus, generation of antibodies to factor VIII represents an appropriate immune response to a foreign protein. However, spontaneous anti–factor VIII antibodies can also arise in patients without congenital hemophilia.[18] In these cases, the anti–factor VIII antibodies are autoantibodies against the patient's own factor VIII. This state has been referred to as acquired hemophilia.

In either of the above scenarios, the patient can have profoundly decreased factor VIII levels that are refractory to treatment with factor VIII replacement, since the antibodies neutralize the transfused factor that is given. The level of anti–factor VIII antibodies can be determined by running a Bethesda assay. Inhibitors that have low Bethesda assay levels (<5 units) can usually be overcome by administration of very large doses of factor VIII. However, in the case of inhibitors with a high level Bethesda assay, overcoming the inhibitor with factor VIII is not possible. In such cases, several products can be given, as detailed below.

Porcine Factor VIII

The utility of porcine factor VIII is its limited cross-reactivity with antibodies against human factor VIII. Thus, in a hemophilia A patient who has formed anti–human factor VIII antibodies, or in a patient with an autoantibody against factor VIII, porcine factor VIII may circumvent such an inhibitor.[19,20] Levels and potency of anti–factor VIII antibody inhibitors can be determined by a Bethesda assay. Values of Bethesda assays specific for human versus porcine factor VIII activities can be juxtaposed to determine whether a given patient's anti–factor VIII antibody cross-reacts with porcine factor VIII. Some patients who are initially responsive to porcine factor VIII rapidly develop antibodies against porcine factor VIII and may become refractory to subsequent treatment. At present, porcine factor VIII no longer is available in North America.

Mutant Factor VIII

A second strategy to circumvent anti–factor VIII antibodies is the expression of novel recombinant forms of human factor VIII in which the immunodominant epitopes have been modified or deleted. A number of different modifications have been made and are in the process of being developed for human use. Like porcine factor VIII, these products should have good efficacy in patients with anti–factor VIII antibodies. However, whether patients treated with altered factor VIII will subsequently develop antibodies to neo-epitopes introduced by the modification remains to be determined.

Recombinant Factor VIIa

Recombinant factor VIIa (rFVIIa), commercially called NovoSeven, functions in theory by promoting hemostasis through the tissue factor pathway. Since factor VIII is not involved in the tissue factor pathway of coagulation, anti–factor VIII inhibitors do not interfere with extrinsic pathway coagulation. This clever approach has shown efficacy in treating anti–factor VIII inhibitors. Since rFVIIa requires tissue factor to promote clot formation, it works selectively at sites of injury or bleeding. Accordingly, the risk of eliciting a thrombosis or consumptive coagulopathy is decreased. The exact mechanism by which rFVIIa functions is likely more complicated than simple tissue factor pathway activation, as interactions with the platelet surface appear to play a role in the clinical efficacy of rFVIIa.

rFVIIa has clear efficacy for the treatment of anti–factor VIII inhibitors and factor VII deficiency, which are the current FDA-approved indications for this drug. However, rFVIIa is being used with increasing frequency for off-label treatment of a wide variety of clinical bleeding situations including trauma, surgery, hepatic coagulopathy, Glanzmann thrombasthenia, Bernard-Soulier syndrome, and reversal of over-anticoagulation with warfarin sodium (Coumadin) and fondaparinux.[21,22] In addition, rFVIIa is used prophylactically to lower INR prior to mildly invasive procedures such as a liver biopsy in a patient with hepatic coagulopathy. The potential efficacy in these settings suggests that factor VIIa has mechanisms of action in addition to extrinsic pathway activation. Reports of small groups of patients and isolated cases have suggested efficacy of rFVIIa in each of the above settings, and it has been suggested that rFVIIa can essentially be used as a universal hemostatic agent.[23] However, there have also been reports of limited efficacy and several instances of increased morbidity or mortality from rVIIa usage.[24–27] In general, the utility and danger of using rFVIIa in these off-label settings has yet to be tested by clinical trials with sufficient size and proper randomization to allow evidence-based decisions.[28] Careful attention should be paid to ongoing studies that assess the benefit and risk of rFVIIa usage for the above indications.

Prothrombin Complex Concentrates (PCCs)

Prothrombin complex concentrates (also known as factor IX complex concentrates) consist of plasma fractions that are significantly enriched for the vitamin K–dependent clotting factors. A number of different methodologies for preparation of PCCs have been described, leading to a variety of products that have been available since the 1960s. Because PCCs

contain large amounts of factor IX, they have been used in the treatment of hemophilia B. In addition, since PCCs contain all the vitamin K dependent–factors, they can achieve rapid reversal of overmedication with warfarin sodium without requiring the large volume and slow administration time of multiple FFP units. PCCs also have efficacy in overcoming factor VIII inhibitors, likely by a mechanism similar to that of rFVIIa, in which the extrinsic pathway promotes clotting in a FVIII–independent manner.

Although PCCs have good efficacy for promoting hemostasis in the context of an anti–factor VIII inhibitor, adverse events have been observed with a greater frequency than for other treatments such as rFVIIa.[29] Such events include thrombosis, thrombophlebitis, pulmonary embolism, and disseminated intravascular coagulation (DIC) and can lead to significant morbidity and mortality.[29] It has been argued that since the methodology for manufacturing PCCs has improved, adverse events are less frequent. Nonetheless, the safety profile of PCCs remains inferior to that of other treatments such as rFVIIa.

Treatment of Congenital Hemophilia B

Congenital hemophilia B is a deficiency of factor IX, for which the only existing therapy is replacement of factor IX with factor IX concentrates. Like factor VIII concentrates for the treatment of hemophilia A (see above), factor IX concentrates are available both as human plasma–derived product and as a recombinant human product expressed in tissue culture.[30] PCCs also contain considerable amounts of factor IX and were the mainstay of treatment for hemophilia B in the past. However, while PCCs can achieve hemostasis in a patient with factor IX deficiency, they are no longer the product of choice given the high rate of adverse thrombotic events described above.

The same issues of safety, efficacy, and cost apply to factor IX concentrates. Both plasma-derived and recombinant factor IX show excellent efficacy in the treatment of hemophilia B.[30] However, since the plasma-derived product comes from multiple donors, there is a risk of disease transmission. Purified factor IX is obtained from screened donors, and the product is subjected to treatments to inactivate known human pathogens. Nevertheless, the risk of infection, although low, is not zero. Moreover, emerging pathogens, which are not currently screened and against which the inactivation procedures may be ineffective, are a persistent concern. Thus, when possible, the recombinant factor is the product of choice.

Treatment of Factor XI Deficiency (Hemophilia C)

Deficiency of factor XI is a rare genetic disorder found predominantly in individuals of Ashkenazi Jewish or French Basques descent.[31,32] The bleeding diathesis that accompanies factor XI deficiency is typically milder than that seen in hemophilia A or B. However, bleeding can become a problem during invasive procedures, surgeries, dental procedures, childbirth, and injuries. Interestingly, the extent and frequency of bleeding does not correlate with the levels of factor XI.[31] Thus, a bleeding history is typically more predictive of the need for prophylaxis than a measurement of plasma factor XI levels alone. Treatment of factor XI deficiency can be achieved by infusing large volumes of fresh frozen plasma (FFP), often in combination with inhibitors of fibrinolysis.[33] Owing to the dilute nature of fresh frozen plasma (FFP), volume overload may be limiting. Although not currently available in the United States, there is a plasma-derived factor XI product.[34] However, use of plasma-derived factor XI concentrates has been associated with thrombosis in up to 10% of patients treated,[34] especially in the elderly, and DIC has also been observed. Thus, there is considerable risk to the use of factor XI concentrates. It has been suggested that treatment with inhibitors of fibrinolysis are therefore contraindicated in conjunction with factor XI concentrates. Recently, rFVIIa has shown potential efficacy in the treatment of both congenital factor XI deficiency and acquired deficiency due to anti-XI autoantibodies.[31,34–37]

Treatment of von Willebrand Disease (vWD)

von Willebrand factor (vWF) is a multifunctional protein that is intimately involved in platelet-initiated clotting at the site of vascular injury.[38,39] Through separate protein domains, vWF binds to subendothelial collagen that is exposed after vessel injury and to glycoprotein Ib on platelets. vWF is synthesized as a multimer, resulting in a high-avidity molecule with multiple binding sites. Thus, when multimeric vWF binds to collagen, it provides a high-avidity docking site for circulating platelets. In this way, vWF is the lynchpin of platelet-initiated clotting.

Defects in vWF result in disorders of platelet-based hemostasis, collectively referred to as vWD. A variety of mutations have resulted in the description of at least six distinct subtypes of vWD.[40] A detailed description of vWD subtypes is outside the scope of this chapter. However, specifics of each subtype will be referred to as they relate to factor-based replacement treatments.

Types 1 and 3 vWD are quantitative defects due to decreased levels of vWF. Type 1 has moderately decreased levels of vWF, whereas levels of vWF are extremely low or absent in type 3 vWD. Mature vWF is stored in the Weibel-Palade bodies of endothelial cells. The administration of DDAVP (desmopressin) results in a sudden release of vWF from the Weibel-Palade bodies. Thus, in the case of type 1 vWD, DDAVP may cause sufficient increases in endogenous vWF release such that no replacement therapy is needed. Since essentially no vWF is synthesized in type 3 vWD, DDAVP has no efficacy in this setting. Thus, administration of replacement vWF is indicated in type 3 vWD patients and in type 1 patients who do not have an adequate response to DDAVP or who require prolonged therapy. Type 2 vWD is a qualitative defect in which vWF levels are typically normal or only slightly decreased, but the function of vWF is defective.[41] Thus, DDAVP may have only limited efficacy in type 2 vWD, since higher levels of a malfunctioning molecule are being induced. In the case of type 2B vWD, DDAVP has been considered to be contraindicated because the defective vWF in this case has an increased binding affinity for platelets. Thus, increasing the levels of the pathologic vWF may induce thrombosis. There also can be a decrease in platelets in type 2B vWD patients after DDAVP administration. However, this relative contraindication has been challenged in some clinical settings, suggesting that DDAVP may have efficacy in type 2B vWD.[42,43]

In addition to the different subtypes of vWD, there is a platelet-type vWD (also called *pseudo-vWD*), which is similar to type 2B vWD because the disease is caused by an increased

affinity between platelets and vWF. However, in the case of pseudo-vWD, it is a mutation in the glycoprotein Ib on the platelet membrane that causes the gain in affinity.[44] In this setting, appropriate treatment is the transfusion of normal platelets. The administration of vWF would have no efficacy, since it is not the vWF that is defective.

Current highly purified factor VIII preparations contain only low amounts of residual vWF, while less stringently purified factor VIII products maintain a large amount of functional vWF. In particular, Humate-P (Aventis Behring) is a purified VIII/vWF complex that is FDA approved for the treatment of vWD. Humate-P has excellent efficacy in all subtypes of vWD.[45–50] Humate-P is not used to treat pseudo (platelet-type) vWD, since this is a defect in glycoprotein Ib and not in vWF. As for all purified products, there is a residual risk of infectious disease. However, like most plasma-derived products, Humate-P undergoes pathogen inactivation. Currently, no recombinant form of vWF is available. Rare occurrences of thrombosis in vWD patients receiving Humate-P have been reported but are infrequent. Elevated levels of factor VIII in vWD patients may be a risk factor for thrombosis during Humate-P therapy.

Prior to the advent of Humate-P, cryoprecipitate was the replacement factor of choice for vWD, since the factor VIII/vWF complex is significantly enriched in cryoprecipitate. Thus, if Humate-P is unavailable, cryoprecipitate is a viable source of vWF for the treatment of vWD. However, because cryoprecipitate has less vWF and is not subjected to pathogen inactivation procedures, Humate-P should always be the treatment of choice.

Factor XIII

Factor XIII enzymatically crosslinks fibrin after clot formation. This cross-linking contributes significantly to the structural integrity of clots. Accordingly, deficiencies in factor XIII do not interfere with clot formation, but resulting clots are unusually fragile and therefore less effective in maintaining hemostasis.[51] The typical symptom is unusually delayed hemorrhaging after primary hemostasis is achieved.[51] Excessive bleeding from the cut umbilical cord of a newborn is associated with factor XIII deficiency.[52] In addition, there is an increased risk of intracranial hematoma formation.[51]

A recombinant form of factor XIII is currently in human clinical trials and not yet available in the United States. However, factor XIII purified from human plasma is available. As mentioned above, the risk of infection from donors is minimized by pathogen inactivation techniques, but it is not zero. In the absence of purified factor XIII, cryoprecipitate can be used because factor XIII is found in cryoprecipitate. However, since cryoprecipitate is not pathogen inactivated, purified factor XIII is the treatment of choice.

Fibrinogen

As described above, cryoprecipitate can be used as a source of concentrated factor VIII, vWF, and factor XIII when the corresponding purified factor preparations are unavailable. However, the purified factors are the preferred treatment, and cryoprecipitate is seldom substituted. In contrast, cryoprecipitate is the preferred method for replacing fibrinogen, since purified or recombinant factors are not available. Hypofibrinogenemia can be observed as a result of a congenital defect, hepatic disease, or a consumptive process. Cryoprecipitate is also useful in the treatment of bleeding secondary to inactivation of platelets by metabolic waste products that accumulate during renal failure (uremic platelet syndrome).[53] The risk of disease transmission is decreased by donor screening. However, since cryoprecipitate does not routinely undergo pathogen inactivation, chronic use of cryoprecipitate is not recommended when a purified factor product is available (e.g., Humate-P for vWD).

Factors Used to Treat Thrombophilia and Sepsis

Antithrombin

Antithrombin (AT), also called *antithrombin III*, is a naturally occurring protease inhibitor that serves to maintain balance in the coagulation system predominantly by inactivating a number of coagulation factors, including IIa and Xa. In addition, enhancement of AT activity is the mechanism by which heparin achieves its anticoagulant effect. Antithrombin levels can be decreased by a congenital defect or a consumptive process. In either case, AT purified from human plasma is commercially available. In addition to its role as an anticoagulant, AT has anti-inflammatory properties.[54] There is interest in the use of AT to treat the inflammatory component of conditions such as sepsis.[55] As for other purified plasma products, the risk of infectious disease transmission is minimized by pathogen inactivation techniques.

Activated Protein C

Protein C is a natural anticoagulant that, together with its cofactor protein S, inactivates coagulation factors Va and VIIIa. There is a recombinant form of activated protein C (APC) that is available for use in humans (Xigris). However, APC is not used to treat the thrombophilia of protein C deficiency, which is typically managed by pharmacologic anticoagulation or protein C replacement (see below). Rather, APC is FDA approved for use in the treatment of adults with severe sepsis only when such patients have a high risk of death as defined by the APACHE II criteria.[56] Although prospective clinical trials have demonstrated that use of APC increases survival in this population,[57] it is not clear whether this is due to anticoagulant activity, since APC also has anti-inflammatory and anti-apoptotic properties. However, while the mechanism of efficacy in treating sepsis may or may not involve APCs anticoagulant properties, such properties appear to be involved in APC toxicity, since bleeding is the most serious side effect of APC use. Accordingly, APC is contraindicated in patients with increased risk of bleeding in anatomically fragile sites such as the central nervous system. Such conditions were exclusion criteria from the phase III trial of APC for treating sepsis.[57]

Protein C Concentrates

Plasma-derived protein C concentrates have been produced in Europe for the treatment of congenital protein C deficiency.[57–59] The heterozygous form of the deficiency is one of the classic causes of congenital thrombophilia but rarely needs protein C replacement, since most patients are adults and the deficiency is controlled by oral anticoagulant therapy. The homozygous form of the disease causes severe thrombotic events, often at birth, and protein C concentrate can be lifesaving in this setting.[57–59] Although not yet FDA approved, the product may be acquired for compassionate use in the United States.

Recombinant Thrombomodulin

Thrombomodulin is an endothelial cell surface protein that binds thrombin and activates protein C, which subsequently downregulates thrombin generation by inactivating factors V and VIII.[60] It is being developed for the treatment of septic DIC in a way that parallels the use of the recombinant activated protein C mentioned previously.[61]

E. Special Processes and Products

Chapter 26

Leukocyte-Reduced Products

Walter H. Dzik • Zbigniew M. Szczepiorkowski

Recipient exposure to allogeneic donor leukocytes can result in several complications of blood transfusion. To reduce the likelihood of these complications, leukoreduction of red blood cells (RBCs) and platelets is widely practiced. This chapter addresses the basis for the adverse effects of recipient exposure to donor leukocytes and presents the evidence supporting the scientific foundation for leukoreduction of cellular blood products. In particular, we address the biophysical mechanisms involved in the preparation of leukoreduced RBCs and platelets and the biologic mechanisms accounting for febrile nonhemolytic reactions, primary human leukocyte antigen (HLA) alloimmunization, transmission and reactivation of cytomegalovirus (CMV), transfusion-associated immunosuppression, and the adverse effects from transfusion of leukoreduced blood. The reader is referred to other sources for a discussion of additional aspects of leukoreduction, including device evaluations, quality control and cell-counting methods, cost effectiveness, and operational issues.[1–3]

TECHNOLOGIES FOR THE PREPARATION OF LEUKOREDUCED BLOOD

Achieving a 10,000-fold reduction in the leukocyte content of blood requires specialized technologies of leukofiltration or apheresis collection. Numerous factors affect the performance of leukofiltration, including the temperature of filtration, the speed of blood flow through the filter, the number of leukocytes presented to the filter, the protein content of the suspending medium, the platelet content of blood, the use of a rinse step after filtration, the storage age of the blood, and the presence of hemoglobin S in the RBCs to be filtered. Standards in the United States require that leukoreduced components be prepared by a method known to reduce donor leukocytes to residual levels of $<5 \times 10^6$ white blood cells (WBCs) per unit for RBCs and apheresis platelets and $<8.3 \times 10^5$ WBCs/unit for whole blood–derived platelets. Methods to produce leukoreduced apheresis platelets should produce products with $>3 \times 10^{11}$ platelets.

Leukofilter Device Design

Removal of leukocytes from whole blood, packed RBCs, or platelets depends on a combination of barrier filtration and cell adsorption to the filter material. Certain principles of design are common to leukofiltration devices.[4] A large surface area of filter medium is required to allow sufficient opportunity for contact of blood leukocytes with the medium. This requirement for surface area can be met through the use of filter media composed of fibers with a very small diameter (microfibers) or open-cell media that are geometrically like a sponge.

Two different approaches to manufacturing such nonwoven media have been commercially viable. The first is a dry formation process in which a polymer (typically a polyester or polyolefin) is melted and extruded through very fine nozzles into a turbulent gas stream at high velocity to produce a microfiber. The synthetic microfiber is simultaneously stretched and cooled to form thin strands of fibers in a process akin to the making of cotton candy. The microfibers are then collected, matted, and heat compressed to a controlled density. Some variation of this basic technique is used in products from Pall Corporation, Asahi Medical Company, Fresenius AG, and MacoPharma, among others.

A second approach is to prepare superfine glass fiber membranes.[5] Foam-like structures with open-cell geometry contain interconnecting voids that allow a circuitous flow passage. The manufacture of such media derives from principles used in the manufacture of sponges. For example, filters from Terumo Corporation are made with the use of a porous polyurethane medium that exhibits an open-cell architecture.

Because they offer an effective pore size that is extremely small, filter media must be designed to have a hydrophilic surface. Otherwise, the material will fail to "wet" as blood encounters the medium owing to the inherent surface tension of blood. The synthetic materials used in leukoreduction filters—polyester and polyolefin microfibers, porous polyurethane, and glass microfibers—are all naturally hydrophobic. Manufacturers modify the surface chemistry of these materials to increase their ability to "wet." Although prefiltration rinsing with a more hydrophilic liquid (e.g., saline rinse) can wet the filter medium, prerinsing introduces an inconvenience that manufacturers of filters generally wish to avoid.

The volume of blood left inside the filter after filtration is referred to as the "hold-up volume." Filters that have a hard external housing often include a venting step at the end of filtration, which allows sterile air to enter the filter and displace blood that would otherwise have been held up in the device. One manufacturer (MacoPharma, Tourcoing, France) packages the filter medium in a flexible plastic housing that collapses under atmospheric pressure as blood drains out of the filter. U.S. Food and Drug Administration (FDA) guidelines require that the filtration process result in loss of no more than 15% of the original amount of therapeutic blood elements.[6]

The filtration medium is packaged in an external housing, and it is essential that the medium completely fill the

housing, allowing no opportunity for the path of blood to flow around the filter (bypass) and thereby circumvent the leukodepletion medium. To appreciate the stringency required, consider that the leukocyte content of an entire unit of leukoreduced RBC is equal to the leukocyte content of only one drop (100 μL) of nonleukoreduced blood.

Mechanisms of Leukoreduction

Barrier Filtration

Simple barrier filtration, in which the effective pore size of the filter medium is smaller than the size of the leukocyte, is a major mechanism used by leukoreduction filters. Modern leukoreduction filters have an effective pore size on the order of 4 μm. This space is sufficient for passage of platelets and deformable erythrocytes but is able to retain leukocytes. Because effective leukoreduction by barrier-based filtration is tightly linked to the deformability of blood cells, factors affecting cell deformability have an impact on filter performance. Increased leukocyte deformability at higher temperatures probably accounts for the poorer performance of leukofiltration when it is applied to room temperature RBCs compared with refrigerated RBCs (see Biophysical Reasons for Reduced Performance of Leukofiltration, below).

Cell Adhesion

Contact-mediated adhesion between leukocytes and the filter medium also contributes to the performance of leukofiltration devices. For contact to occur, there must be a sufficient dwell time of the blood with the medium. For the cells not to detach from the medium, shear forces of the flowing blood must not be too strong. High flow rates can result in insufficient contact and excess detachment of leukocytes from the medium. Because cell adhesion to filter media involves a complex surface chemistry that is not fully understood, filter media development has been largely determined by experimentation. The nature of the fluid in which cells are suspended, including the plasma protein content and the platelet content, affects the adhesion of leukocytes to synthetic media. Steneker[7] demonstrated that during leukofiltration of fresh RBCs the presence of viable platelets improves the performance of leukofiltration. This has been attributed to sticking of platelets to protein-coated fibers in the filter medium, with subsequent binding of leukocytes to these activated platelets. Ledent and Berlin[8] demonstrated that replacement of plasma with crystalloid can decrease the performance of leukofiltration, presumably by decreasing the concentration of adhesive plasma proteins that participate in leukocyte adhesion to the medium.

Leukofiltration of platelet concentrates presents the added complexity that platelets are naturally adhesive under shear conditions in a plasma environment, as a result of von Willebrand factor–mediated platelet adhesion. Therefore, manufacturers of leukoreduction filters designed for platelets have further modified the surface chemistry of the filter media to decrease binding of platelets to the filter. For example, Nishimura and colleagues[9] documented that by adjusting the molar ratio of positively charged diethyl-amino ethyl methacrylate to negatively charged hydroxyethyl methacrylate, the net surface charge on the filter medium could be adjusted to optimize leukocyte adhesion but minimize platelet adhesion to the medium.

Biophysical Reasons for Reduced Performance of Leukofiltration

The reduced efficiency of leukofiltration applied to warmed RBCs compared with cold RBCs has repeatedly been demonstrated. For example, Beaujean and coworkers[10] split RBCs (storage age, 2 to 10 days) into two equal aliquots, which were then filtered at either 4°C or 37°C. The mean postfiltration leukocyte content was 10-fold higher for units filtered at 37°C. Ledent and Berlin[8] found leukocyte content to be 100-fold higher among units filtered at 37°C compared with 4°C. Sirchia and colleagues[11] studied filtration under conditions designed to mimic bedside use. They found that cold RBCs warmed to room temperature within 90 minutes after removal of the units from the refrigerator. They also documented that as the blood warmed, filtration performance declined, and units failed to meet minimum standards for leukoreduced blood ($<5 \times 10^6$ WBCs/unit). The failure was striking with units containing as much as 100-fold more leukocytes than the upper threshold level for leukoreduction. The performance failure associated with bedside leukoreduction is very important to the interpretation of major clinical trials of leukoreduction technology. For example, both the CMV prevention trial of Bowden and associates[12] and the HLA alloimmunization trial of Williamson and coworkers[13] used bedside filtration with filters subsequently determined to have reduced performance under warm conditions. The performance of newer versions of leukoreduction filters may be less sensitive to temperature. Van der Meer and colleagues demonstrated enhanced performance at 4°C, but the difference between the results at 4°C and at 22°C was less than that seen in earlier studies.[14]

Several other factors may reduce the effectiveness of leukofiltration. Excess shear force and resulting cell detachment from the filter medium may be an important consideration when bedside leukofiltration is combined with mechanical blood delivery systems that may "pull" blood through the filter at excessive rates. Postfiltration rinsing of filters may also occur during bedside transfusion and has been documented to result in leukocyte detachment. Filtration of excessive volumes of blood or of blood containing excessive numbers of leukocytes can overwhelm the capacity of the filter medium, leading to ineffective leukoreduction.

Leukofiltration of RBCs has been shown to be less effective if the donor blood carries hemoglobin AS (sickle trait).[15,16] Poor leukofiltration is believed to result from reduced red cell deformability among hemoglobin AS erythrocytes under conditions of reduced oxygen tension and pH, such as occur within the filter. Stroncek and colleagues showed that increasing the oxygen tension of hemoglobin AS blood prevented the poor filtration performance.[16] Decreased deformability of red cells containing hemoglobin S at low oxygen tensions is presumed either to directly "clog" the filter or to reduce the effective area of filter medium available for retention of leukocytes. Because sickle trait is relatively common in some donor populations, the frequency of failure of leukoreduction by filtration may be higher than expected.

Leukoreduced Components Prepared by Apheresis

Modern apheresis devices are able to collect concentrates of platelets or RBCs that are leukoreduced during collection; this is referred to as process leukoreduction. Several devices

are licensed for collection of one or more components (for review see ref. 17).

The Amicus apheresis system (Baxter Healthcare, Round Lake, Ill.) is a widely used apheresis system for the preparation of leukoreduced platelets. The device incorporates three design features to achieve leukoreduction: active interface control, autoelutriation, and fluid flow dynamics. An optical interface detector is positioned within the separation chamber to monitor changes in the platelet interface. The system recirculates some of the donor plasma into the interface in order to separate platelets from leukocytes by elutriation. Just as a wind blows lightweight leaves but not heavy objects across a street, plasma pumped through the interface dislodges the platelets but not the leukocytes into the collection path. The collection path for platelet collection is in the opposite direction to the flow path for the return of RBCs and plasma to the donor, promoting further separation between donor platelets and donor leukocytes.

The Trima Accel automated system separates platelets from donor whole blood using a single-stage channel design. Whole blood enters the channel and separates under centrifugation into component layers. Platelets are drawn out through a specially designed conical-shaped chamber (LRS chamber) while plasma and RBCs are returned to the donor. The LRS chamber, originally developed for the COBE Spectra System, combines centrifugal separation technology with saturated fluidized particle-bed dynamics to achieve a natural separation of WBCs from platelets. White cells are separated from the platelets according to the fluid dynamics of the separation chamber, the sedimentation velocity of the platelet and white cell components, and the plasma flow rate through the chamber. These dynamics result in a flow geometry that traps donor leukocytes in the lower levels of the LRS chamber while allowing platelets in the upper levels of the chamber to exit toward the platelet collection/storage bag. Under some donor collection conditions, leukocytes can spill out of the chamber into the collection product. The Trima System uses a computerized on-line process that monitors for conditions known to increase the risk of WBC contamination in the platelet product.

Quality Control of Leukoreduction

Because any leukoreduction process may fail, standards for quality control testing exist. No common standard exists for all nations, however. For example, in the United States the American Association of Blood Banks standards require that 95% of the units sampled meet threshold requirements for residual leukocyte content.[18] In Europe, the threshold level of residual leukocytes is $<1 \times 10^6$/unit.[19] Validation of new leukoreduction methods or devices and ongoing quality control evaluation requires counting methods specifically designed for the extremely low concentration of white cells found in leukoreduced blood components. A variety of techniques are available based on microscopy, flow cytometry, and the polymerase chain reaction.[20] No standards address the relative proportion of residual leukocyte subpopulations in leukoreduced blood. Although different leukocyte subpopulations are relevant for different biologic effects attributed to donor leukocytes, there is no convincing clinical outcomes evidence that any particular leukoreduction technique is superior to any other for removal of specific leukocyte subpopulations.[21,22] Currently, all methods of leukoreduction that meet the threshold standard for total number of residual donor leukocytes are considered equivalent.

In addition to the reduced performance of leukofiltration resulting from filtration at higher temperature or in the presence of hemoglobin S blood, quality control studies of leukoreduction have documented occasional process problems with both leukofiltration and apheresis technologies. For example, Kao and colleagues[23] reported quality control data from the Trial to Reduce Alloimmunization to Platelets (TRAP). Using a propidium iodide stain and microscopic chamber counting, they found that 7% of apheresis platelets and 5% of pooled platelets contained more than 5×10^6 residual donor leukocytes. For RBCs, 0.3% to 2.7% of units failed to meet leukoreduction standards depending on the particular leukofilter used. In addition, they reported substantial losses of platelets and RBCs as a result of the process of leukofiltration. Although quality control monitoring of apheresis platelets documents reliable performance of collection systems,[17] as with leukofiltration, the apheresis process can fail. Sudden changes in the rate of blood entering the machine or pauses in blood flow during collection will disturb the centrifugal separation of blood in the chambers and may interrupt the controlled flow paths upon which the cells travel during separation. These interruptions can lead to "spillover" of leukocytes into the platelet collection stream. Manufacturers have attempted to engineer alarms into the software that will alert operators to conditions that might result in the failure to collect a leukoreduced product. The leukocyte content of these collections can then be tested to determine whether the product is leukoreduced. Although refinements in filter design and apheresis technology have improved leukoreduction, there remains value in continuous quality monitoring of blood component preparation and modification.

CLINICAL INDICATIONS FOR LEUKOREDUCED BLOOD COMPONENTS

Three prominent clinical indications for leukoreduced cellular blood components are (1) to reduce the frequency of febrile nonhemolytic transfusion reactions among patients with a prior history of such reactions, (2) to decrease the incidence of HLA sensitization and platelet refractoriness among patients with hematologic malignancy, and (3) to reduce the risk of transfusion-transmitted CMV infection among susceptible recipients[24] (Box 26–1). Leukocyte-reduction technology has also been applied to other clinical situations in the absence of strong evidence but with an expectation of benefit.

Universal Leukoreduction

Use of leukocyte reduction for all cellular components is controversial[25] (Box 26–2). Several countries adopted policies

BOX 26–1 ***Indications for Leukoreduced Blood Components***

- Reduce rate of recurrent febrile nonhemolytic transfusion reactions (FNHTRs)
- Reduce rate of HLA alloimmunization among hematology-oncology patients
- Reduce rate of cytomegalovirus transmission to susceptible recipients

BOX 26–2 ***Pros and Cons of Universal Leukoreduction***

Pro:

- Patients with selected indications to receive leukoreduced blood will be more likely to receive leukoreduced units
- Inventory management is streamlined

Con:

- Large clinical studies fail to demonstrate clear or consistent benefit of leukoreduction on proposed transfusion-associated immunosuppression
- Adds >$500 million each year to health care costs
- May adversely affect adequacy of blood supply in setting of recalls of leukoreduction devices; may interfere with supply of blood donors of African ancestry (sickle trait blood)
- Removes physician choice from product selection

in favor of universal leukoreduction for different reasons. The decision was linked to a program of hemovigilance in France, to concern over the potential for spread of transmissible spongiform encephalopathies by donor leukocytes in the United Kingdom, and to a general reorganization of blood services in Canada. In the United States, the Blood Product Advisory Committee of the FDA voted in 1998 in favor of universal leukoreduction in the absence of any consideration of cost to the health care system and sponsored a conference in 1999 that was geared toward implementation of universal leukoreduction. However, such implementation was never mandated, and studies estimated that universal leukoreduction would cost more than $500 million per year in the United States with uncertain benefit. Nevertheless, despite the absence of any regulatory mandate, some major blood suppliers in the United States elected to sell only leukoreduced products, and thus the proportion of leukoreduced blood components has gradually increased to more than 50% in the United States.

The potential benefit of universal leukoreduction among surgical patients was investigated in a retrospective multicenter study conducted in Canada.[26] The study was not a prospective randomized trial, but rather compared outcomes in two cohorts of patients—one cohort transfused prior to the implementation of universal leukoreduction ($N = 6982$) and the other cohort transfused after universal leukoreduction ($N = 7804$). The study did not examine outcomes among all transfusion recipients (universal impact) but rather focused on three groups of more critically ill patients: those with trauma, those undergoing cardiac surgery, and those undergoing major orthopedic surgery. Because these patient groups receive large numbers of transfusions, they were expected to be most likely to demonstrate any beneficial effect of leukoreduction. Prior to adjustment for potential confounders the authors found a slightly lower risk of overall mortality (unadjusted odds ratio = 0.87, 95% CI, 0.76–0.99, $P = 0.04$) among cohort 2 (leukoreduced group). However, when the results were adjusted for the effects of cardiac medications, the adjusted odds ratio failed to show a statistically significant benefit for leukoreduction. Moreover, within each of the three major patient categories studied (trauma, cardiac surgery, orthopedic surgery), the adjusted odds of death were not statistically different in the cohort of patients receiving leukoreduced components compared with the cohort receiving control RBCs. Finally, it was noted that unadjusted mortality rates also declined among *non-transfused* patients during the two periods of observation. Major secondary outcomes included infections, length of stay in intensive care, or total hospital length of stay—none of which were statistically different in the two cohorts of patients. In particular, the authors noted that the lack of effect on infectious complications argued against a transfusion-related immunosuppression effect. No difference was seen in the two groups for the proportion of patients requiring ventilation support, hemodynamic support, or renal dialysis. In addition, there was no observed beneficial effect of leukoreduction among the subgroups of patients receiving larger doses of blood (>5 units per patient) compared with those receiving fewer transfusions.

One large prospective randomized clinical trial specifically examined the potential benefit of conversion from selective leukoreduction to universal leukoreduction.[27] This single center study randomized 2780 patients to receive either prestorage leukoreduced RBCs and prestorage leukoreduced apheresis platelets (for patients needing platelets) versus nonleukoreduced RBCs (buffy coat not removed) and nonleukoreduced pooled whole blood–derived platelets. All patients (adult, pediatric, medical, and surgical) not meeting standard criteria for leukoreduced blood (see Box 26–1) were eligible. Because individual patient consent was not required, the study had the advantage that all eligible candidates were automatically enrolled (no exclusions). The primary outcome measures were in-hospital mortality, length-of-stay in hospital following transfusion, and total hospital costs. The study found no difference among primary outcomes for patients assigned to leukoreduced versus nonleukoreduced blood components. This large trial was powered to have an 85% chance to detect a 15% difference in the primary outcome with a 95% confidence. Several secondary outcomes were examined all of which also showed no benefit to leukoreduction. These included antibiotic use to treat infection following transfusion (all patients) or to treat postoperative infection (surgical subset), length of stay in intensive care, postoperative length of stay, or readmission rates to hospital. There was a statistically nonsignificant trend toward fewer febrile nonhemolytic reactions in the group assigned to receive leukoreduced blood. Subset analysis restricted to heavily transfused patients failed to show any advantage for leukoreduced blood. The study provided randomized, controlled trial evidence for a lack of measurable benefit resulting from conversion to universal leukoreduction.

Prevention of Febrile Nonhemolytic Transfusion Reactions by Leukoreduction

One of the first indications for the use of leukocyte filters was prevention of febrile nonhemolytic transfusion reactions (FNHTRs). Original studies suggested that the frequency of FNHTRs to packed RBCs is reduced when the residual leukocyte content is less than 5×10^8 WBCs/unit.[28–32] Although FNHTRs are one of the most common transfusion reactions experienced by recipients of blood components, they are also relatively easy to manage. Many, but not all, FNHTRs can be prevented by leukoreduction of blood components.

Fever is a hallmark and part of the clinical definition of FNHTR. In addition to fever, patients may experience chills, rigors, cold, a sense of discomfort, headache, and nausea. Because the pathophysiology of fever involves a rigor/chill

response before the temperature rises, the initial signs of an FNHTR may be only rigors without temperature elevation. Therefore, the presence of early-onset fever should not be required to diagnose an FNHTR.[33,34] FNHTRs tend to develop toward the end of a transfusion, and in 10% to 20% of cases reactions are noted after the transfusion has been discontinued. Such clinical observations underline the fact that reactions are dose related and require time to develop.

Pathophysiology of Fever

Fever is one of the oldest signs and symptoms recognized in medicine. Fever results from cytokine generation by activated monocytes, macrophages, and Kupffer cells. The involved cytokines, including interleukin-1β (IL-1β), IL-6, interferon-β (IFN-β), and tumor necrosis factor-α (TNF-α), are polypeptides that act on the organum vasculosum of lamina terminalis (OVLT).[35] The OVLT interacts with the preoptic area of the hypothalamus. In the case of TNFα, the induction of cyclooxygenase-2 in brain blood vessels leads to increased production of prostaglandins (mainly prostaglandin E_2)[36] and subsequently to fever.[37] Engel and associates[38] reported the peripheral blood levels of cytokines measured in patients with fever and neutropenia. The median peak concentration for IL-6 was 400 pg/mL (range, 100 to 41,000 pg/mL); for IL-8, it was 1025 pg/mL (range, 600 to 26,000 pg/mL); for TNFα, less than 10 pg/mL; and for IL-1β, 17 pg/mL (range, <10 to 36 pg/mL).

Incidence and Mechanisms of FNHTR

The reported incidence of FNHTR depends on the transfused component. Transfusions of nonleukoreduced RBCs are associated with 0.5% to 6.0% risk, whereas transfusions of platelet concentrates carry a risk as high as 20% to 30%.[39–41] This significant difference between RBCs and platelet concentrates can be attributed to different mechanisms involved in development of febrile reactions.

FNHTR CAUSED BY DESTRUCTION OF TRANSFUSED DONOR LEUKOCYTES

First proposed in the 1960s, the original hypothesized mechanism suggests that donor leukocytes react with recipient antileukocyte antibodies, causing the donor cells to release endogenous pyrogens (cytokines) (Fig. 26–1). This mechanism is consistent with the prevention of FNHTRs by leukoreduction of donor blood, and it is supported by studies of de Rie and colleagues,[42] Decary and colleagues,[43] Perkins and colleagues,[44] Brubaker,[45] and others[46] that documented the high prevalence of antilymphocyte or antigranulocyte antibodies in the sera of patients who experienced FNHTRs. However, the mechanism fails to account for the fact that FNHTRs are more common among recipients of platelets compared with packed RBCs, and it failed to explain the observation that FNHTRs may occur among men with no history of prior transfusions. In addition, the mechanism can be challenged because leukocytes are not known to store IL-1 and TNF[47] suitable for "immediate release" upon destruction by recipient antibody. Finally, the original mechanism fails to explain why patients with anti-HLA antibodies have febrile reactions when transfused with leukocyte-reduced platelet concentrates.

FNHTRS CAUSED BY PASSIVE TRANSFER OF CYTOKINES

In a series of simple and well-designed experiments, Heddle and associates[48] focused attention on the plasma constituent of stored platelet concentrates, rather than the platelets themselves, as the source of febrile reactions after transfu-

Figure 26–1 Mechanisms underlying febrile nonhemolytic transfusion reactions. (Adapted from Klein HG, Dzik WH, Slichter SJ, Hillyer CD, Silberstein LE. Leukocyte-reduced Blood Components: Current Status. Educational Program, American Society of Hematology, 1998, pp 154–177.)

sion of platelet concentrates. The authors selected 4- and 5-day-old platelet concentrates. Using centrifugation, the platelet-poor plasma was separated from the platelet pellet, which was resuspended in fresh plasma. Patients were then transfused with both components in random sequence, with a 2-hour washout period between transfusions. Signs and symptoms suggestive of FNHTR were assessed. Transfusions of the platelet-poor plasma obtained from stored platelet concentrates were associated with a significantly higher rate of FNHTR, compared with the resuspended platelet pellets. The authors concluded that soluble substances that had accumulated in the plasma during platelet storage were primarily responsible for febrile reactions in the older platelet concentrates. Increased levels of two cytokines, IL-1β and IL-6, were present in stored platelets and correlated with the frequency of observed reactions.

Mechanism of cytokine accumulation in platelet concentrates. Cytokines include a large family of molecules involved in innate immunity and cell signaling. After release by mononuclear phagocytes, T lymphocytes, and several other cell types, cytokines bind to specific receptors on target cells. Cytokine receptor chains cluster, and their intracellular portions are phosphorylated by Janus kinases (Jaks). The phosphorylation step is required for the Src homology–2 (SH-2) portion of the Jak to bind to the receptor. SH-2 facilitates binding of a signal transducer and activator of transcription (STAT) protein. After phosphorylation, these STAT proteins form homodimers, which migrate to the nucleus and bind to nuclear factors such as nuclear factor-κB (NF-κB) or activation protein–1 (AP-1) transcription factors. The transcription factors then activate genes involved in innate immunity.[49]

A number of reports showed increased accumulation of cytokines, especially IL-1β, IL-6, IL-8, TNF-α, and RANTES (regulated on activation, normal T expressed and secreted), with prolonged storage of platelet concentrates.[50–52] Increased cytokine levels were observed especially on the fourth and fifth day of storage. Stack and Snyder[51] assayed 2-, 3-, 4-, and 5-day-old platelet concentrates for IL-1β, IL-6, IL-8, and TNFα. Although IL-8 was the cytokine most frequently detected, IL-8 is not regarded as a fever-producing cytokine. Increased IL-1β was observed in the units with elevated IL-8. In general, the highest levels of IL-8 were found in the units with the longest storage times and highest leukocyte counts. Only 8% and 10% of tested units showed detectable levels of IL-6 and TNFα, respectively. Leukoreduction before storage prevented the accumulation of IL-8 and IL-1β to day 5 of storage. This study underscored the importance of storage time and initial number of leukocytes before storage in the generation of cytokines.

Palmer and coworkers[53,54] combined results of their two studies and showed that cytokine accumulation during storage of platelet concentrate correlated with the number of leukocytes present before storage. Units with a leukocyte concentration greater than 100/μL resulted in detectable levels of IL-8 and IL-1β. Although prestorage leukoreduction prevented cytokine accumulation, leukoreduction had no beneficial effect on markers of platelet activation such as P-selectin, transforming growth factor-β1 (TGF-β1), platelet-derived growth factor AB (PDGF-AB), von Willebrand factor, and serotonin. These results were confirmed in a study by Fujihara and colleagues,[55] who showed that accumulation of platelet-derived RANTES and TGF-β1 was independent of leukocyte concentration but correlated with platelet concentration.

Monocyte activation. Monocytes are a major constituent of the leukocyte population in platelet concentrates. They are also capable of secreting cytokines, namely IL-1β, IL-6, and TNFα. Several authors have investigated monocyte activation in platelet concentrates as a potential explanation for cytokine accumulation. Muller-Steinhardt and associates[56] studied the influence of storage time, temperature, and type of anticoagulant on the capability of mononuclear cells to secrete cytokines. Mononuclear cells were harvested on days 1, 3, and 5 from platelet concentrates stored under routine conditions, and the response to mitogenic stimulants, such as lipopolysaccharide (LPS), phytohemagglutinin, and staphylococcal enterotoxin B, was evaluated by measuring secretion of IL-1β, IL-2, IL-6, and IFNα. The ability of monocytes to secrete cytokines did not change significantly during the first 3 days of storage and decreased to 25% to 50% of original levels by day 5 of storage. Mitogenic response of mononuclear cells was significantly higher at 37°C than at 22°C. These findings showed that under normal storage conditions mononuclear cells in platelet concentrates preserve the ability to synthesize and secrete cytokines for at least 5 days. Heddle and coworkers[57] demonstrated that cytokine accumulation during storage is temperature dependent. Platelet concentrates were split into two identical portions, one of which was stored for 5 days at 22°C and the other at 4°C. Cytokines failed to accumulate in the aliquots stored at 4°C.

Grey and associates[58] reported in vivo activation of monocytes in platelet concentrates. They analyzed platelet concentrates for leukocyte and monocyte total count, CD14 and CD16 monocyte-associated antigen expression, and IL-1β and IL-6 concentrations on days 1, 2, 3, 4, and 5. The analyzed monocytes expressed increased levels of CD14 (LPS receptor) and CD16 (FcRIII), which are both markers of activation, starting on the first day of storage. On day 3, more than 50% of platelet concentrates had an increased IL-6 concentration. The elevation of IL-6 and IL-1β correlated with the number of monocytes in the unit on day 1. However, increased IL-6 levels occurred earlier during storage. Several hypotheses have sought to explain the delay between monocyte activation and detectable elevation of interleukins. TNFα and IL-1 are known to induce IL-1 synthesis and together with PDGF can stimulate IL-6 synthesis.[59] Both IL-1α and IL-1β were found in the cytoplasm of resting and thrombin-activated platelets.[60] It is possible that the cumulative effect of PDGF and IL-1 derived from platelets reaches a threshold concentration necessary to trigger monocytes to generate additional cytokines such as IL-8 and IL-6. This hypothesis is supported by the findings by Aye and colleagues[53] indicating that, despite uniform release of PDGF from platelets during preparation and storage, only components with high leukocyte content had a detectable level of cytokines.

Mononuclear cells in stored platelet concentrates may be activated by other mechanisms. Activation of monocytes by the plastic used in storage bags was studied by El-Kattan and coworkers.[61] Whole blood–derived platelets were stored in plastic bags made of polyolefin (POF), and apheresis platelets were stored in the bags made of polyvinyl chloride (PVC). Mononuclear cells showed preferential adherence to POF compared with PVC. This adherence was associated with

increased mean cytokine levels (IL-1β, TNF, IL-6) that were 11- to 48-fold higher in POF bags compared with PVC bags.

FNHTRS CAUSED BY CYTOKINE PRODUCTION BY RECIPIENT MACROPHAGES

A third mechanism for FNHTRs depends on cytokine release by the recipients' own macrophages (see Fig. 26–1). It has been proposed that recipient antibody bound to donor-cell antigen may form an immunocomplex that serves to activate recipient macrophages to release inflammatory cytokines.[62] This mechanism does not depend on release of preformed stored cytokines contained within donor leukocytes but acknowledges that immunocomplexes are a known stimulus for macrophage activation. Indirect support for this hypothesis comes from a number of observations, including the development of fever among alloimmunized recipients of prestorage leukoreduced platelets; fever after transfusion of platelets to patients with immune thrombocytopenia or drug-induced thrombocytopenia; fever among recipients of incompatible RBC transfusions; and the fever reactions to the cellular portion of platelet concentrates seen in the study by Heddle and associates[48] cited earlier.

CYTOKINE CONCENTRATIONS IN VIVO AND IN VITRO

Sacher[63] attempted to establish the causality between cytokines and FNHTR. IL-6 levels were measured in vivo before and after transfusion in a group of 42 patients. Acute transfusion reactions occurred in 26 patients. The mean post-transfusion IL-6 level was 3.7-fold higher than in pretransfusion specimens. Patients without acute reactions had insignificant increases in IL-6 levels. Unfortunately, the concentration of IL-6 in the transfused components was not measured, leaving uncertainty as to the origin of the cytokine elevation (i.e., a blood component or the recipient).

In the absence of conclusive clinical trials, one may question which cytokines found in platelet concentrates may cause FNHTRs. The amount of TNF-α known to cause fever and chills is approximately 5 to 10 μg/m,^{2} or 8500 to 17,000 ng of TNF-α for a 70-kg person.[64,65] In order to achieve such an amount after transfusion of a blood component, the amount of TNF-α present should be approximately 28,000 to 56,000 ng/L in a 300-mL unit, or 170,000 to 340,000 ng/L in a 50-mL unit. However, the measured levels of TNF-α in platelet concentrates were far below this level, with the highest reported concentration being 1890 ng/L and the median concentration in the range of 42 to 571 ng/L.[51–53] The data suggest that passive transfer of TNF-α cannot be solely responsible for symptoms observed in patients with FNHTR. The situation is slightly different for the other endogenous pyrogen, IL-1. This cytokine can cause clinical symptoms at concentrations as low as 10 to 100 ng/kg, corresponding to 700 to 7000 ng in a 70-kg recipient.[66–68] The maximum measured levels of accumulated IL-1 in platelet concentrates vary from 143 to 26,000 ng/L, with medians ranging from 14 to 5250 ng/L.[51–53] These median values correspond to 0.7 to 260 ng in a 50-mL unit or 4.2 to 1560 ng in a 300-mL unit. Passive transfer of such quantities of IL-1 might be able to cause fever in a 70-kg person.

Cytokine accumulation during storage of RBCs is not likely to contribute to FNHTRs. The measured levels of cytokines are substantially lower than found in the platelet concentrates.[69] Stack and coworkers[70] analyzed levels of IL-1β, IL-6, and IL-8 in leukoreduced and nonleukoreduced RBCs. Over 42 days of storage, IL-1β accumulated in the nonleukoreduced units from the baseline of 0 ng/L to 5 to 13 ng/L. Thus, a 42-day-old RBC with 125 mL of supernatant would passively transfer 0.6 to 1.6 ng of IL-1. These values are substantially below the 700 to 7000 ng required to achieve fever levels (see above).

SUMMARY OF THE MECHANISMS OF FNHTRS

FNHTRs to RBCs are best explained by release of recipient cytokines (immunocomplex mechanism). In particular, cytokines do not accumulate during refrigerated storage of red cells to levels considered sufficient to induce a clinical febrile response.[69,70] In contrast, FNHTRs to platelets that have not undergone prestorage leukocyte reduction can be attributed to either accumulation of cytokines during storage or to release of recipient cytokines (immunocomplex mechanism). When prestorage leukoreduced platelets are implicated in FNHTRs, the most likely mechanism is the immunocomplex in which donor platelets are the target of recipient antibodies. Such reactions may be a clinical tip-off to the presence of HLA antibodies and refractoriness.

Clinical Evaluation of FNHTRs

Studies[30,31] in chronically transfused patients with thalassemia have documented that leukoreduction is a highly effective means to prevent FNHTRs to RBCs. Current methods of leukoreduction—whether done before storage, just before blood issue, or at the bedside—are capable of reducing the residual donor leukocyte concentration to levels well below those that result in FNHTRs. Moreover, owing to refrigerated blood storage (and in contrast to platelet concentrates), RBCs do not accumulate clinically important levels of cytokines during storage. Indeed, fever reactions to properly leukoreduced RBCs are sufficiently rare that patients who receive leukoreduced RBCs and experience fever should be evaluated for the presence of hemolytic reactions due to RBC blood group incompatibility and for the presence of bacterial contamination of the transfused product. In contrast to RBCs and as described earlier, FNHTRs to platelet concentrates are much more common and are not completely eliminated by leukoreduction. Patients experiencing FNHTRs to platelet concentrates should be evaluated for platelet increments, for evidence of alloimmunization, for drug-induced platelet refractoriness, for bacterial contamination of platelets, and for passive transfer of antibodies to ABO antigens from donor to recipient.

Prevention of HLA Alloimmunization

Alloimmunization to HLA donor antigens is a well-recognized complication of blood transfusion. Clinical consequences of HLA alloimmunization include FNHTRs, renal allograft rejection, and platelet refractoriness. There are many nonimmune causes of platelet refractoriness, including fever, use of amphotericin B, drug-related antiplatelet antibodies, hypersplenism, consumptive coagulopathy, and idiopathic thrombocytopenic purpura. Because these conditions contribute to platelet refractoriness, no studies have documented that prevention of alloimmunization by leukoreduction prevents *bleeding complications* due to platelet refractoriness. Nevertheless, prevention of HLA alloimmunization is generally regarded as an important benefit of leukoreduction.

After the demonstration in rodents by Claas and colleagues that leukocytes and not platelets are responsible for primary

alloimmunization,[71] leukoreduction of blood components was the subject of numerous clinical trials assessing alloimmunization to donor HLA antigens. The reported rate of anti-HLA alloimmunization due to unmodified components in randomized controlled trials varied from 20% to 50% in the control arm, with median incidence of 42%.[72] Meta-analysis of eight controlled, randomized trials demonstrated a 70% reduction in the incidence of HLA alloimmunization in the group of patients who received leukoreduced blood components.[13,72–79] The same report identified a corresponding reduction in platelet refractoriness. The currently recommended level of leukoreduction to prevent allosensitization is less than 5×10^6 WBCs/unit (3 to 17 WBCs/μL).[80,81]

Immune recognition of foreign donor cells requires at least three fundamental elements: binding of the antigen to the antigen receptor, binding of costimulatory molecules mediating cell–cell contact, and local elaboration of cytokines and appropriate cytokine receptors. In whole blood, the majority (70%) of class I HLA antigen is found on the surface of platelets, which express 50,000 to 100,000 copies at their surface.[82,83] The rest of the HLA molecules are distributed among RBCs (3%), granulocytes (2%), lymphocytes (2%), and plasma (23%). Platelet concentrates contain approximately 3.4 mg of HLA molecules, of which 3.2 mg (94%) are associated with platelets, 0.2 mg is in plasma, and 17 μg are present on leukocytes.[82] Therefore, most of the HLA antigens in nonleukoreduced platelet concentrates are found on the platelets themselves. For this reason, it may seem counterintuitive that leukoreduction decreases the risk of alloimmunization.

The recipient of platelet concentrates is exposed to different forms of HLA antigens: soluble class I/II antigens in the plasma, class I/II antigens on cell fragments shed from leukocytes and platelets during processing and storage, class I antigens present on intact platelets, and class I/II antigens expressed on leukocytes. The route by which the antigen presentation occurs influences the likelihood of alloimmunization. Indeed, an important feature of transfusion-induced alloimmunization is the availability of two different sets of antigen-presenting cells (APCs): those of donor origin and those of recipient origin. Stimulation of recipient T or B cells by donor APCs has been called "direct" alloimmunization. In contrast, stimulation by recipient APCs, presenting peptides of donor origin, has been called "indirect" alloimmunization. The data derived from clinical trials of leukoreduction and from basic research suggest that the direct alloimmunization pathway plays a more important role in transfusion-induced alloimmunization.[82]

Direct Alloimmunization Pathway

Direct alloimmunization refers to the process by which recipient immune cells respond directly to donor HLA antigens without the processing of donor antigens by recipient APCs. The mixed lymphocyte reaction is an in vitro example of direct T-cell recognition. Direct sensitization to donor class I antigens results when the recipient is exposed to donor cells bearing class II structures. The route by which donor peptides derived from class I antigens are directly presented has not been precisely delineated. Class II–positive donor cells might carry within the peptide-binding groove oligopeptides representing the cell's own HLA class I antigen. It is known, for example, that a proportion of the endogenous peptides eluted from major histocompatibility class (MHC) molecules are from degraded self-MHC molecules.[84,85] In addition, donor CD4+ T cells were shown in a rodent transfusion model to serve as direct APCs to recipient CD8+ cells.[86]

Kao and del Rosario provided additional direct experimental evidence for the importance of HLA class II cells in transfusion-induced alloimmunization to class I MHC antigens.[87] Using a rodent transfusion system, they compared alloantigen response to transfusion of unmodified donor mononuclear cells versus transfusion of mononuclear cells that were first depleted of cells bearing class II MHC antigens. Alloantibodies against class I MHC antigens were generated in 100% of mice infused with unmodified mononuclear cells, whereas only 25% of mice transfused with the modified components became alloimmunized. This study confirmed the validity of direct immunization mediated by donor APCs and also showed variability in response among different strains.

Clinical studies of transfusion-induced HLA alloimmunization suggest that donor class I peptides presented by class II cells are more immunogenic than intact class I molecules found on donor platelets. The failure of platelets to directly provoke immunization presumably reflects the absence of critical costimulatory molecules on platelets. For example, Gouttefangeas and coworkers showed that HLA class I molecules from platelets cannot directly induce allogeneic CD8+ cytotoxic T-cell response in vitro.[88] Moreover, pure platelet suspensions are unable to stimulate cells in a mixed lymphocyte reaction. Because leukoreduction depletes blood of cells bearing the combination of HLA antigens and costimulatory molecules, and because neither RBCs nor platelets display the combination of class I antigen, costimulatory molecule, and relevant cytokine, leukoreduction of RBCs or platelets prevents direct HLA alloimmunization.

Indirect Allorecognition Pathway

Indirect allorecognition refers to the process by which recipient APCs first engulf donor cells and then process donor antigen for redisplay to the recipient immune system. Donor cells, cell fragments, and soluble donor antigens undergo endocytosis by phagocytosis, macropinocytosis, or a clathrin-mediated process.[89] The proteins are degraded to small peptides within a specialized lysosomal compartment termed the *MHC class II compartment* of the recipient APCs. The peptides are then loaded onto class II molecules as follows. The MHC invariant chain (Ii), a chaperone molecule that guides α and β chains of class II molecules from the endoplasmic reticulum, is digested proteolytically. A fragment of Ii, the class II–associated Ii peptide (CLIP), remains associated with αβ dimers and occupies the peptide-binding groove. In addition, HLA-DM stabilizes the αβ complex and facilitates binding of the peptides to the peptide-binding groove. The allogeneic peptides are then loaded into the MHC class II groove, replacing CLIP or HLA-DM.[90] Empty class II molecules—those that contain neither peptide, invariant chain, nor HLA-DM—are unstable and are degraded in the low pH compartment of the lysosomes. Because HLA-DM is found at a fivefold lower concentration than HLA class II in the late endosomal compartments, excess self-HLA class II molecules are presumably degraded and their peptide fragments recycled.

Since transfusion typically results in alloimmunization to class I HLA antigens, trafficking of class I molecules in donor APCs is of special interest to transfusion science. Although

no evidence currently documents that class I peptides are concentrated in the MHC class II compartment, current technical limitations make it hard to determine the proportion of peptides bound to class II that originated from class II compared with class I molecules.[91] However, Turley and colleagues reported that class I HLA molecules can accompany class II HLA molecules from the endoplasmic reticulum, where the class I molecules may be potentially degraded and their peptides loaded onto class II structures ultimately expressed on the surface of the cell.[92]

Expression of costimulatory molecules by APCs is presumably required for transfusion alloimmunization. Both CD80 and CD86 can bind to CD28 found on T-helper (Th) lymphocytes, thereby promoting T-cell activation. Activated helper T cells in turn increase their expression of CD40 ligand (CD40L) and the IL-2 receptor. CD40L interacts with CD40 present on B cells to induce activation of B cells and expression of B7-2, and later B7-1, on the surface. Resting B cells do not express CD80/CD86 on their membrane, but on activation, either by cytokines or by activated T lymphocytes, B cells are able to fully interact with T cells and follicular dendritic cells in germinal centers. In addition, a profile of cytokines secreted by T cells is needed for B-cell activation and antibody synthesis. A Th1 response is associated with increased secretion of IL-2 and IFN-γ whereas a Th2 response is characterized by secretion of IL-4, -5, -10, and -13. The cytokines generated by T cells allow for B-cell proliferation, maturation, and antibody production.

Investigators have attempted to dissect the pathway of antigen processing by recipient APCs in response to transfusion. Bang and colleagues[93] developed a system in which allogeneic platelets were incubated with the recipient's APCs in the presence of various compounds that potentially affect intracellular peptide processing, such as IFN-γ, aminoguanidine, L-arginine, colchicine, ammonium chloride, chloroquine, brefeldin A, and a cytosolic proteasome inhibitor (MG115). The pulsed APCs (enriched spleen macrophages) were then injected into recipients, and antidonor IgG production was evaluated. Forty-five percent of recipients developed alloantibodies after two infusions, and all recipients were alloimmunized by the sixth transfusion. Two patterns of response were observed. The first was consistent with the classic endosome-dependent processing of exogenous antigen and resulted in production of IgG1 antibodies. The second pattern was insensitive to both chloroquine and pH, suggesting a nonendosomal pathway, and led to an IgG2a alloimmune response.

Clinical Studies of Leukoreduced Components to Prevent Alloimmunization

There have been eight prospective, randomized, clinical trials of filter-leukoreduced blood components to prevent platelet alloimmunization. The populations studied were patients with chronic thrombocytopenia and, in most of the investigations, acute myelogenous leukemia. As reviewed by Heddle[94] and by Vamvakas,[72] these trials varied greatly in experimental design. For example, they differed in such fundamental issues as exclusion criteria, definition of alloimmunization and platelet refractoriness, methods of leukoreduction, consistency of leukoreduction, and numbers and types of patients enrolled. The majority of studies showed that fewer patients in the study arm receiving leukoreduced components developed lymphocytotoxic antibodies (Table 26–1). However, this difference between groups was less pronounced when the researchers looked at clinically significant platelet refractoriness. Not surprisingly, these studies documented that alloimmunization to platelet-specific antigens was not affected by leukoreduction.

The largest and the most authoritative prospective randomized trial was the TRAP study, which enrolled 268 patients with acute myelogenous leukemia.[79] The results demonstrated conclusively that leukoreduction of blood components reduces the rate of alloimmunization among patients with leukemia. The study also demonstrated that leukoreduced, pooled, whole blood–derived platelets are as effective as apheresis platelets for the prevention of alloimmunization. Although the rate of HLA alloimmunization was higher among patients with a history of prior pregnancy, compared with never-pregnant patients, the alloimmunization rate among previously pregnant patients was lower in the leukoreduced arms than in the control arm. The finding that patients who were previously pregnant might benefit from leukoreduction differed from the results of other studies that showed lack of efficacy of leukoreduction for such patients.[78] Despite the size of the TRAP trial, the measured

rate of platelet refractoriness was low: 16% in the control arm and 7% in the study arm ($P = 0.03$). Platelet refractoriness was strictly defined as corrected count increments of less than 5000/μL on two sequential transfusions. The study defined the primary outcome as concurrent development of both antibodies and platelet refractoriness. Platelet refractoriness (defined as described) that was present within 2 weeks after the development of antibodies constituted alloimmune platelet refractoriness. By these criteria, 13% of patients in the control arm and 3% of those in the treatment arm had alloimmune platelet refractoriness ($P = 0.004$).

A recent study on the value of prestorage leukoreduction on alloimmunization comes from Canada.[95] In this one center study a retrospective analysis was performed on 617 patients with hematologic malignancies who were treated with chemotherapy and/or stem cell transplantation. The authors note that the level of alloimmunization strongly correlates with history of previous transfusion of nonleukoreduced components, pregnancy, and transfusion of more than 13 doses of platelets. This study carries a number of caveats including its retrospective design; multi–year span, which may have affected treatment outcomes; and population of patients who routinely receive leukoreduced components in the United States. It is then difficult to interpret the observed decrease of alloimmunization. Though the number of patients with pre-existing antibodies was small, there was no evidence that universal leukoreduction affected their level of alloimmunization.

The collective results from existing clinical trials support the use of leukoreduced components to prevent primary alloimmunization in patients with acute myelogenous leukemia who are receiving induction chemotherapy. However, there have been few studies of leukoreduction and alloimmunization in other patient groups. Because treatment of leukemia is itself immunosuppressive, the impact of leukoreduction may be different in other patient groups, and the efficacy of leukoreduction for prevention of HLA alloimmunization among nonleukemic patients has not been formally demonstrated.

The prevention of alloimmunization in immunocompetent patients has not been studied extensively. We can get a glimpse of the potentially complicated issues from two recently published reports. The group from Leiden studied the influence of buffy coat depletion with additional pre- or poststorage leukoreduction on formation of new anti-WBC and/or anti-RBC alloantibodies in patients undergoing cardiac surgery.[96] Approximately 75% of patients in this study had no detectable antibodies against WBC or RBC prior to transfusion. After a single transfusion episode with multiple units of either buffy coat–depleted RBCs, prestorage leukoreduced RBCs, or poststorage leukoreduced RBCs, approximately 10% of patients in each group developed anti-WBC antibodies. In addition, the patients who were alloimmunized prior to transfusion increased their panel reactivity in almost 30% of cases, again without significant difference between study arms. This study raises a question of a failure of leukoreduction to protect nonimmunosuppressed patients from developing both anti-WBC and anti-RBC antibodies. An interesting observation was published by Ohto and colleagues.[97] The group performed a multicenter randomized trial of bedside leukoreduced (average content of 0.3×10^6 WBC/unit) versus buffy coat–depleted (average content 1234×10^6 WBC/unit) RBCs administered to nonimmunocompromised patients undergoing cardiac surgery. The authors noted lack of statistically significant difference between the groups with the rate of alloimmunization of 17% and 5%, respectively. This somewhat counterintuitive result may reflect the competence of the immune system in the study groups. These two reports raise an important question of generalizability of leukoreduction as a means to prevent alloimmunization in both immunosuppressed and immunocompetent individuals. Additional studies are clearly needed to answer this important question.

Cytomegalovirus: Transmission and Reactivation

CMV is a member of the herpes family of DNA viruses and is a significant pathogen for immunocompromised individuals. Approximately 2 decades of clinical and basic research provide evidence that CMV can be transmitted by donor leukocytes and that transmission can be reduced by leukoreduction. Clinical trials documenting the effectiveness of leukoreduction as a means to reduce the risk of transmission of CMV have been reviewed elsewhere.[98,99] Testing of donors for evidence of antibodies to CMV is another widely practiced method for reducing the risk of CMV transmission by blood components. Please see Chapter 46 for a detailed discussion.

Clinical Trials of Transfusion-Transmitted CMV and Leukoreduction

From among the many studies on transfusion-transmitted CMV, two clinical trials stand out. Both were large studies and involved bone marrow transplant patients.

Bowden and associates performed a prospective, randomized trial of leukoreduction versus CMV serologic screening for prevention of transfusion-transmitted CMV.[12] Patients undergoing bone marrow transplantation (BMT) who were CMV seronegative were randomly assigned to receive either CMV-seronegative nonleukoreduced blood components ($N = 252$) versus CMV-untested leukoreduced blood products ($N = 250$). The primary outcome was CMV infections occurring after day 21 from transplant. This outcome was selected because infectious outcomes before day 21 of transplant were considered to be the result of exposure *prior* to the study period. The primary analysis found no difference in the rate of CMV infection (CMV− = 0 1.3% vs LR = 2.4%, $P = 1.00$) or CMV disease (CMV− = 0% vs LR = 2.4%, $P = 1.00$). The study was designed to have 80% power to detect a 5% difference between the two study arms with 95% confidence. In a secondary analysis that included all events during days 0 to 100, there was still no statistical difference in the rate of CMV infection, but the rate of CMV disease was lower in the CMV-seronegative arm (CMV− = 0% vs LR = 2.4%, $P = 0.03$). The authors concluded that leukofiltration was an effective alternative to the use of seronegative blood components for prevention of transfusion-transmitted CMV. The study sparked lively controversy on the difference between the primary and the secondary analysis of the data.[100] It was also noted that patients could receive up to 6 units of "nonstudy" blood and remain in their original assigned arm although these violations appeared to account for only one infection in each arm.

The interpretation of the Bowden paper involves two important details. Firstly, RBCs in the leukoreduced arm were leukofiltered at the bedside. It was not known at the time of the study that bedside leukoreduction of RBCs has a very high failure rate.[11] Thus, patients assigned to the

leukoreduction arm of the study received products that had far inferior leukoreduction compared with today's technology. On the other hand, the sensitivity of assays for CMV serologic screening has remained stable since the Bowden trial. Thus, if the trial were repeated today, it would be reasonable to expect an even lower rate of CMV transmission in the leukoreduction arm. The Bowden study also provides some insight into the issue of HLA refractoriness and fatal hemorrhagic outcomes. While higher rates of HLA alloimmunization and platelet refractoriness would be expected to have occurred in the patients randomized to receive *nonleukoreduced* blood, there was no observed impact of study arm assignment to overall survival. Thus, any degree of benefit from leukoreduction regarding prevention of fatal bleeding due to platelet refractoriness was so small as to be undetectable in a trial of 500 BMT patients. Although the Bowden study remains the best clinical trial to date on the topic of CMV transfusion-transmitted CMV, its findings need to be interpreted in light of the technology used to prepare leukoreduced blood.

A second major study among BMT patients was the report by Nichols and colleagues, who took an entirely different approach and reached opposite conclusions.[101] They compared CMV infection in two cohorts of patients. One cohort was treated from 1994 to 1996 and received mostly CMV-seronegative blood components. When these were not available for individual patients, the patients received leukofiltered blood from CMV-positive donors. The second cohort was patients treated from 1996 to 2000 who received similar blood components except that platelet support was provided with apheresis platelets collected on machines designed to produce leukoreduced platelets (process leukoreduced apheresis platelets). The study design was, therefore, a comparison of "before versus after" introduction of apheresis leukoreduced platelets. The principal finding of this study was that the incidence of transfusion-transmitted CMV was 1.7% in the first cohort versus 4.0% in the second cohort ($P = 0.05$). Because the two cohorts were sequential in time, the results are subject to other confounding factors that differed during the two periods. Furthermore, the incidence of CMV in the "before" cohort (1.7%) may have been unusually low that year by chance. This is suggested by the authors' observation that the usual background incidence of transfusion-transmitted CMV in their population is 2% for patients transfused exclusively with CMV-seronegative donor blood. The authors did find that patient exposure to leukofiltered blood from CMV-seropositive donors was marginally higher during period two. For example, the mean number of leukofiltered RBCs from CMV-seropositive donors was 0.08 units in period one and 0.15 in period two (P = NS).

Analysis of the data provided complex results. Using univariate analysis for the cohort 2 patients, the odds of CMV infection by transfusion rose weakly in association with receiving CMV *seronegative RBCs* (OR = 1.00–1.02, $P = 0.05$). A positive odds ratio was also found for cohort 2 patients who were transfused with process leukoreduced apheresis platelets from CMV seropositive donors, but the association was also rather weak (OR = 1.00–1.06, $P = 0.05$). However, in multivariate analysis of the same cohort 2 data, the above-mentioned associations with higher odds of CMV infection were no longer significant, but a third factor was associated with higher odds of CMV infection—namely, transfusion with leukofiltered RBCs from a CMV-positive donor. This latter finding is unexpected because the principal change in blood support between cohort 1 and cohort 2 did not involve RBCs but rather was a change from leukofiltered platelets to process leukoreduced apheresis platelets. One possible explanation is that the use of leukofiltered RBCs from CMV-seropositive donors may simply have been a marker (correlate) for sicker patients whose increased transfusion demands resulted in the blood bank selecting CMV-seropositive donors. Indeed, patients acquiring CMV from transfusion had a statistically higher overall blood requirement than those not acquiring CMV infection.

It is difficult to make firm policy decisions based on the Nichols study. Although the authors' conclusions were that serologic screening might be superior to leukofiltration, other interpretations of the findings are possible: leukofiltration of platelets might be superior to process leukoreduction by apheresis, the use of CMV-seropositive leukofiltered RBCs might have been a correlate for sicker patients, patients from cohort 1 may have had by chance an unusually low background incidence of CMV, or the results may have been confounded by other influences.

Comparative trials of leukoreduction versus CMV serotesting have not shown a clear benefit of one method over the other. Although a meta-analysis concluded that serologic testing was superior,[102] that analysis was dominated by results of the Bowden trial and the Nichols trial. As noted above, the Bowden study used bedside leukofiltration prior to the discovery that bedside leukofiltration has a high failure rate and the Nichols trial was a "before-versus-after" study design with several methodological weaknesses.

CMV Is Present in Blood Donors as a Latent Infection in Mononuclear Cells

Almost all studies of the epidemiology of CMV infection identify that the virus is common in healthy individuals and that the prevalence of serologic markers for prior infection increases with age. Although carriers of CMV may intermittently shed virus in their saliva, they do not have continuous viremia. Rather, CMV is present in latent form—the viral genome is present, but gene expression is limited and infectious virus is not produced. Blood cells, endothelial cells, tissue macrophages, stromal cells, and neural cells are all sites of CMV latency.

Leukoreduction reduces the likelihood of transfusion-transmitted CMV because the virus is tropic for leukocytes and is not found in erythrocytes, platelets, or plasma of healthy blood donors. CMV DNA is difficult to recover from leukocyte DNA of healthy carriers. Whereas CMV is found in polymorphonuclear leukocytes of patients with *active* infection, viral DNA is found in mononuclear cells of healthy donors.[103,104] Polymerase chain reaction (PCR) has been used to demonstrate that blood monocytes and macrophages (rather than T and B cells) are the principal sites of latent CMV infection. In particular, it appears that CMV is tropic for peripheral blood cells expressing either CD13 antigen[105] or CD14 antigen.[106]

Using reverse transcriptase PCR, Taylor-Wiedeman and colleagues[107] demonstrated that monocytes from latently infected, healthy, seropositive individuals failed to transcribe CMV genes. However, when the cells were cultured in vitro after exposure either to granulocyte-monocyte colony-stimulating factor plus hydrocortisone or to phorbol 12-myristate 13-acetate plus hydrocortisone, they differentiated into macrophages and expressed messenger RNA for the CMV early-intermediate gene. However, late CMV gene transcripts

were not produced, and the cells failed to shed complete virus, suggesting an arrest in productive viral transcription at the early gene phase.

Few Mononuclear Cells in Healthy Donors Harbor CMV

Among healthy blood donors, the proportion of mononuclear cells infected with CMV bears directly on the likelihood that 3- to 4-log leukoreduction will prevent CMV transmission by transfusion. Earlier studies reported that CMV immediate-early gene transcripts were present in 0.03% to 2% of peripheral blood mononuclear cells from healthy seropositive individuals.[108] Subsequently, Slobedman and Mocarski[109] analyzed the proportion of infected cells by PCR and in situ hybridization and by quantitative competitive PCR. Using normal donors undergoing granulocyte colony-stimulating factor mobilization of hematopoietic progenitors, they found that 0.004% to 0.01% of mononuclear cells contained viral genomes at a copy number of 2 to 13 genomes per infected cell. Among healthy blood donors who are not undergoing growth factor–mediated mobilization, the proportion of infected cells presumably would be lower. These findings generate a plausible explanation for the ability of leukoreduction to reduce the transmission of CMV. If a unit of blood contains approximately 10^7 monocytes and if 1 in 10,000 to 1 in 100,000 monocytes are infected, then the unit contains 10^3 to 10^2 latently infected cells. Therefore, a 3- to 4-log leukoreduction may be expected to render the unit noninfectious. However, in vitro experiments in which units were spiked with CMV-infected fibroblasts failed to show complete clearance of CMV transcripts when the leukofiltered blood was tested by PCR.[110] On the other hand, it is unlikely that clinical infections in humans result from exposure to a single latently infected cell, even though the threshold level required to acquire infection is not known. For example, quantitative studies of the level of viremia in patients after liver transplantation have documented that levels greater than 10^4 genomes per milliliter are required for infections to become symptomatic.[111]

Seronegative Healthy Subjects May Test Positive for CMV DNA

Although serologic testing has proved of great practical value for reducing transfusion-related CMV, some investigators have reported that a minority of serologically negative samples may be positive for CMV DNA when tested by PCR. CMV-seronegative, PCR-positive blood donors could account for the finding that patients supported with CMV-seronegative units experience a 1% to 4% rate of CMV transmission, as measured by CMV seroconversion, viremia, or viruria.[112] However, the actual incidence of CMV DNA-positive seronegative donors remains uncertain. In the largest study to date, Roback and colleagues[113] used two previously validated PCR assays and found that none of 514 CMV seronegative donor samples were DNA positive. This result is in sharp contrast to Bevan and associates[114] who studied 312 CMV-seronegative samples and found that 25% were positive for CMV DNA. There is no clear explanation for these different results although numerous methodological details sharply affect the performance of the tests. For example, Rahbar and co-workers[115] reported that CMV-seronegative blood donors lacked antibodies to the laboratory strain AD 169—a strain commonly used as the antigen target in serologic assays, but that 36% of these CMV "seronegative" individuals had antibodies to clinical isolates of CMV prepared from infected patients. On the other hand, Krajden and colleagues[116] found that the method of DNA extraction affected the performance of CMV DNA tests. Among 101 samples obtained from CMV-seropositive blood donors, the frequency of a positive PCR result was 0%, 1%, or 8% depending on which of three different kits were used to isolate DNA for testing.

Infection with Multiple CMV Strains Has Not Been Shown to Result from Transfusion

Molecular typing methods have demonstrated that some patients are infected with more than one strain of CMV. Using restriction enzyme analysis, Chou[117] compared the patterns of isolates among 36 pairs of recipients of CMV-seropositive renal allografts. Although material from the kidney donors was not analyzed, they found paired recipients who shared the same kidney donor also demonstrated a common CMV strain that was not present in the recipients before the transplant. Follow-up studies confirmed that solid organ transplants were capable of infecting recipients with a second strain of CMV.[118] Multiple-strain infection was also reported by Chandler and colleagues,[119] who found molecular evidence for multiple-strain infection among four of eight women attending a clinic for sexually transmitted diseases. Spector and associates[120] reported multiple-strain infection in two persons with serologic evidence of infection with the human immunodeficiency virus (HIV) who were diagnosed with acquired immunodeficiency syndrome. However, the interpretation of studies of second-strain infection has been confounded by the fact that strain mutations develop under the selective pressure of antiviral therapy.[121] These mutations lead to a different pattern of restriction digest, which can be misinterpreted as a second independent strain.

Recognition of second-strain infection via organ transplantation or multiple sexual contacts raises the possibility of transfusion-transmitted second-strain infection and the question of whether CMV-seropositive transfusion recipients should receive CMV–reduced risk blood components. The risk of second-strain infection by transfusion remains only theoretical to date, because no such cases have been reported. Using restriction endonuclease analysis, Winston and coworkers[122] observed no second-strain infections in a study of 18 allogeneic bone marrow transplant recipients who developed CMV during the course of their treatment.

Reactivation of Latent CMV by Transfusion of Allogeneic Donor Leukocytes

Decades ago, the hypothesis was put forward that allogeneic transfusion would result in an in vivo mixed lymphocyte reaction and that this immunologic stimulus might result in reactivation of latent CMV infection.[123] The hypothesis that allogeneic donor leukocytes would result in viral reactivation in the recipient following transfusion was definitively tested in the Viral Activation Transfusion Study (VATS).[124] The study was a multicenter, randomized, double-blind trial comparing the effects of allogeneic blood with and without leukoreduction on the outcomes of 531 patients already infected with HIV-1 and CMV. A total of 3864 units of RBCs were transfused. The primary study outcome measures were mortality and plasma levels of HIV (RNA assay) measured 7 days after transfusion. The results showed no survival advantage with the use of leukoreduced blood, with 151 deaths in the leukoreduced group and 138 deaths in the control group. Median survival was 13 months

(leukoreduced) versus 20.5 months (control), P = NS. When adjusted for baseline prognostic factors (CD4 count and plasma HIV RNA level) survival was statistically worse in the leukoreduced group (relative hazard for death 1.35 compared with nonleukoreduced, 95% CI, 1.06–1.72). The use of leukoreduced blood did not delay the time to onset of new opportunistic infections and had no effect on the frequency of transfusion reactions. No changes were seen in plasma HIV RNA levels after transfusion. In addition, there was no advantage to leukoreduction for a variety of secondary outcome measures including CMV DNA levels, CD4 cell counts, cell activation assays, or plasma cytokine levels. This study provided substantial evidence against the hypothesis that donor leukocytes cause clinical viral reactivation. Because HIV-infected individuals are at high risk for immune breakdown, the failure to observe increased infections in the control group relative to the leukoreduced group also cast doubt on the role for leukoreduction as a means to abrogate any proposed immunosuppressive effect of transfusion. In summary, the available clinical evidence fails to support a role for leukoreduction in the prevention of viral reactivation.

Donor Leukocytes and Immunosuppression

Allogeneic blood transfusion has been suggested to induce a mild state of immunosuppression. The original suggestion for this effect arose from the observation in 1973 by Opelz and associates[125] that allogeneic transfusions given before renal transplantation resulted in improved allograft survival. Although the allograft effect was confirmed by numerous subsequent reports, including studies conducted in the era of modern antirejection therapy,[126] the exact mechanism has never been conclusively explained. In 1981 Gantt[127] questioned whether transfusions might also down-regulate host antitumor immunity, thereby resulting in either an increased rate of tumor relapse or a shorter interval from primary tumor resection to time of relapse. Subsequently, the hypothesis of transfusion-related immunosuppression was extended to include concern that transfusion might increase the frequency of postoperative bacterial infections. A detailed account of the possible immunosuppressive effects of transfusion was published by Vamvakas and Blajchman.[2]

Common Themes in Experimental Studies of Transplant Tolerance and Transfusion

Four themes regularly appear in experimental studies of transfusion and immune tolerance to organ transplantation: recipient immune conditioning, the histocompatibility relationship between donor and recipient, the presentation of antigen, and the persistence of donor antigen. First, experimental induction of transplant tolerance appears to require proper *"conditioning" of the recipient.* Conditioning regimens usually consist of mild immunosuppression with anti–T cell globulins, chemotherapy, or corticosteroids. Presumably these agents weaken the immune response in such a way as to prevent the transfused cells or proteins from provoking alloimmunization and to allow the transfused cells or proteins to persist within the recipient long enough to induce tolerance.

Second, antigen-specific tolerance induction appears to depend on the proper *relationship between the MHC antigens of the donor and those of the recipient.* Transfusions from donors who are highly mismatched at MHC loci appear more likely to provoke alloimmunization than immunosuppression. Immune tolerance may depend on partial histocompatibility matching of donor and recipient. However, the details of the MHC relationship required for the induction of tolerance are poorly defined and appear to vary among species and with the experimental conditions. In human studies, HLA class II antigen matching appears to be particularly relevant. For example, van Twuyver and associates[128] studied 23 untransfused, first-time renal allograft recipients, each of whom was deliberately transfused before transplantation with donor fresh blood containing approximately 7×10^8 leukocytes. After transfusion, cytotoxic T-cell precursors directed against donor antigen targets were measured. Ten patients demonstrated a significant decline in the level of antidonor T-cell response at 1 month after transfusion. Nine of them were found to share one HLA haplotype (HLA-B and HLA-DR match) with their donor. In contrast, those patients transfused with mismatched blood maintained strong anti–T cell responsiveness after transfusion.

Third, the *dose and molecular presentation of transfused antigens* may affect whether the recipient response is directed toward alloimmunization or tolerance. Evidence for the induction of tolerance by infusion of large intravenous doses of antigen (high-zone tolerance) has existed for years in experimental immunology. The molecular presentation of donor antigen may also play a critical role in the immune response of the transfusion recipient, and there is evidence supporting a role for both cell-associated antigen and soluble antigen as agents for the induction of experimental tolerance. Experimental work from several laboratories has demonstrated that soluble HLA antigens can downregulate in vitro immune responses by several different mechanisms.[129] For example, peptides from the nonpolymorphic 3 region of the class I HLA molecule were able to inhibit the differentiation of cytotoxic T cells in response to an alloantigen stimulus,[130] and soluble HLA peptides can inhibit NK cells.[130] Soluble HLA antigen or other factors released from leukocytes form the basis for the hypothesis that prestorage leukoreduction would reduce an immunosuppressive effect of transfusion. However, Dzik and colleagues[131] found no evidence that the measured soluble HLA antigens differ in units of RBCs stored with or without prestorage leukoreduction. In contrast, Ghio and associates[132] measured increased concentrations of soluble class I HLA antigens and soluble Fas ligand in units of RBCs and platelets during storage. They found that concentrations of soluble antigens and Fas ligand were proportionate to the number of residual donor leukocytes in the blood components.

Finally, the *persistence of donor antigen* in the recipient is a common finding in experimental models for the induction of transplant tolerance.[133] Studies have focused on "microchimerism"—the persistence of low levels of donor cells in the graft recipient. There appears to be little doubt that microchimerism accompanies tolerance. However, it is uncertain whether the persistence of donor cells contributes to the induction of tolerance or is merely a consequence of tolerance. Microchimerism after clinical solid organ transplantation is unquestionably present and has been verified by numerous assays. Microchimerism with fetal cells may also exist in women after normal pregnancy and delivery.[134] Whether microchimerism develops after blood transfusion is controversial. Lee and colleagues[135] reported evidence for extended microchimerism after blood transfusion. Using

a PCR assay directed against donor-type HLA genes, they detected donor signal in one recipient for up to 1.5 years after transfusion. Of note, the transfusions occurred in the setting of trauma and included infusions of fresh blood. In follow-up studies, Lee and colleagues reported that recipients of leukoreduced blood also demonstrated microchimerism.[136]

Immunologic Mechanisms Suggested for Transfusion-related Immunosuppression

At various times, one or more of the following four immunologic mechanisms has been suggested as mechanisms for a proposed immunosuppressive effect of blood transfusion: clonal deletion, anergy, active suppression, and indirect effect via viral transmission.

CLONAL DELETION

Central thymic tolerance to self-antigens develops when T cells are deleted during thymic education. Thymic tolerance to foreign antigens can be induced by the inoculation of MHC peptide into the recipient thymus. These peptides are presumably taken up by recipient APCs and displayed as if they were self-antigens. For example, Chowdhury and colleagues[137] were able to induce prolonged cardiac allograft acceptance in a rat model by intrathymic injection of synthetic class I allopeptides. Whether central tolerance is relevant for blood transfusion is unknown. It is conceivable that donor HLA peptide present in blood becomes localized in the recipient thymus gland. Because the thymus involutes with age, the role of central thymic tolerance may be more relevant for pediatric transfusions than for those given to adults.

T-cell clones may also undergo deletion outside the environment of the thymus gland. Activation-induced apoptosis occurs when T cells respond to antigen via their T-cell receptor but are not sustained by costimulatory molecules or by proper cytokine support. Normally, for any given environmental antigen, only approximately 1 in 10^5 to 1 in 10^6 T cells have a matching T-cell receptor and are able to respond to the antigen. However, in the setting of an allogeneic HLA stimulus, such as occurs with organ transplantation or blood transfusion, approximately 1% to 10% of T cells are able to respond. This remarkable finding is the basis of the strong blastogenic response of the routine mixed lymphocyte culture. It is possible that this large activation signal leads to considerable activation-induced apoptosis of recipient cells and subsequent peripheral clonal deletion.

DEVELOPMENT OF CELLULAR ANERGY

Multiple lines of experimental evidence demonstrate that immune activation of T cells depends on the cell's receiving not only a primary signal (the antigen signal) but also a secondary signal known as a costimulatory signal. Certain costimulatory molecules send an activation signal, whereas others send an anergy signal. One hypothesis concerning the immunomodulatory effect of blood transfusion suggests that during refrigerated blood storage donor leukocytes undergo alterations that result in anergy signals to recipient T cells. There is little direct experimental evidence to support this contention, although Minchef and coworkers,[138] using a rodent transfusion model, reported that refrigerated storage resulted in both necrosis and apoptosis of donor cells. Other experimental evidence has also suggested that apoptotic cells are directly immunosuppressive.[139]

INDUCTION OF SUPPRESSOR CELLS

One important hypothesis for the immunosuppressive effect of blood transfusion suggests that transfusion may drive the recipient toward T-cell suppression. In a series of experiments in mice, Chen and associates[140] showed evidence for tolerance induced by a suppressor T cell found in the spleen. BALB/c mice (H-2d) were donors of cardiac allografts to MHC-disparate CBA/Ca (H-2k) recipients. In the absence of any conditioning, the recipients promptly rejected the cardiac allografts. Transplant tolerance was induced by pretransplantation blood transfusion from the donor after conditioning with nonlytic antilymphocyte globulin. Under these conditions, the animals retained the cardiac allografts for more than 100 days. Splenic lymphocytes taken from these tolerant animals were then transferred to naive CBA/Ca animals, which were then tolerant of BALB/c heart allografts in the absence of any immunosuppression. In fact, tolerance could be transferred successfully through nine passages of splenic lymphocytes into new animals. The suppressor cell was localized to the CD4+ subset of T cells. Studies, such as this one, that demonstrate adoptive transfer of tolerance argue strongly in favor of a suppressor cell mechanism. Similar findings were reported by Yang and colleagues,[141] who suggested than the CD45RC+ subset of CD4+ T cells accounted for the immunosuppression.

More direct experimental evidence that allogeneic blood transfusion can induce suppressor T cells in recipients comes from the studies of Blajchman and colleagues,[142,143] who examined the potential of transfusions to promote tumor growth in animals. In one series of experiments, animals were first transfused with either unmodified allogeneic blood, leukoreduced allogeneic blood, or syngeneic blood (as a control). After the transfusions, the animals were challenged with an injection of tumor cells. After a waiting period, the animals were sacrificed and the number of pulmonary metastases were counted. The investigators found that transfusion with unmodified blood promoted increased numbers of pulmonary metastases, compared with leukoreduced or syngeneic blood. Moreover, spleen cells transferred to naive animals from animals that had received unmodified allogeneic blood transfusions promoted greater numbers of pulmonary metastases than did spleen cells transferred from animals that had not been transfused or had received transfusion of leukoreduced blood. These findings argue for the induction of suppressor spleen cells in the animals who had received unmodified donor blood.

Further evidence for splenic suppressor cells induced by blood transfusion was presented by Kao.[144] He was able to induce humoral immune nonresponsiveness in CBA mice (H-2k) using transfusions of ultraviolet B–irradiated leukocytes from BALB/c (H-2d) donor mice. Ultraviolet B irradiation is known to interfere with the expression of costimulatory molecules (see earlier discussion). When spleen cells from the tolerant animals were transferred to naive CBA recipients, the recipients also became tolerant to BALB/c donor antigens. Presumably, the transferred cells suppressed the ability of CBA recipients to form a humoral immune response.

In humans, direct evidence for the induction of Th2-type suppressor cells by blood transfusion is lacking. However, Kirkley and associates[145] reported in vitro cytokine release in 43 patients transfused with either allogeneic or autologous blood at the time of hip surgery. Mean levels of IL-10

and IL-4 released in vitro were slightly higher among recipients of allogeneic blood, suggesting polarization by allogeneic transfusion toward a Th2 phenotype. However, other studies of transfused patients have not found statistically significant differences in cytokine profiles as a result of transfusion.[146,147]

Clinical Studies of Immunosuppression and Leukocyte Depletion

Whether blood transfusion results in a clinically measurable increase in tumor recurrence or postoperative bacterial infection has never been adequately resolved. The issue is difficult to address experimentally in human subjects. A large number of observational studies have documented that patients who receive transfusions are more likely than their untransfused counterparts to develop tumor recurrence or bacterial infection. This observation, however, represents a correlation and does not imply that the transfusions resulted in these adverse effects. Rather, blood transfusion may simply be a marker that correlates with severity of disease. Moreover, the finding that transfusion correlates with tumor recurrence or bacterial infection does not imply that leukoreduction would have a beneficial effect on the frequency of these complications. The effect of leukoreduction has been addressed by randomized, prospective, blinded clinical trials in which patients are assigned to receive either leukoreduced or nonleukoreduced blood components. In addition, trials that examine outcomes in cohorts of patients transfused before versus after implementation of leukoreduction have been reported. Summarized below and in Table 26–2 are large clinical studies published after the year 2000.

Transfusion and Cancer Recurrence

It was proposed in the 1990s that transfusion would increase the rate of cancer recurrence. This hypothesis was supported by preclinical animal experiments that involved deliberate inoculation of tumor cells[142,143] and by retrospective reports in humans showing an association between transfusion at the time of cancer surgery and the subsequent development of recurrent cancer. However, well-designed clinical trials have not supported the hypothesis that leukoreduction would affect tumor biology. For example, van de Watering and colleagues provided results on long-term cancer recurrence among 697 patients with colorectal cancer who were randomized to receive either leukoreduced or nonleukoreduced (buffy coat–depleted) blood components.[148] They found that the 5-year survival rates (65% leukoreduced; 64% control) and 5-year cancer recurrence rates (28% leukoreduced; 28% control) were nearly identical in the two groups. The study provided randomized controlled trial evidence that leukocyte reduction at the time of cancer surgery did not affect the rate of cancer recurrence.

Transfusion and Postoperative Infection

NONCARDIAC SURGERY

The hypothesis that recipient exposure to donor leukocytes induced some form of immunosuppression was also extensively investigated as a potential cause for post-transfusion infection in surgical patients. Initially, retrospective studies found an association between higher rates of postoperative infection among transfused patients compared with untransfused patients. However, as with cancer recurrence, such studies may have only identified that transfusion was a marker of more serious illness.

Because earlier studies suggested that patients undergoing colorectal surgery were more likely to benefit from leukoreduction technology, Titlestad and colleagues performed a prospective randomized trial in 279 such patients who were randomized prior to transfusion to receive either leukoreduced or nonleukoreduced RBCs.[149] Because only a minority of patients required transfusion, the number of transfused patients receiving leukoreduced RBCs ($N = 48$) or nonleukoreduced RBCs ($N = 64$) was modest. The authors found that the rate of postoperative infection was not different in the two groups. In addition, there was no effect of leukoreduction on mortality or hospital length of stay.

Baron and colleagues[150] recorded infection rates following abdominal aortic surgery in a cohort of patients ($N = 192$) transfused before implementation of leukoreduction and compared them with infection rates of a subsequent cohort of patients ($N = 195$) transfused after implementation of leukoreduction. The two cohorts showed no difference in rates of postoperative infection (leukoreduced 27% [95% confidence of 21–33%] versus control 31% [95% confidence of 25–38%]); no difference in the proportion with severe infection or pneumonia; no differences in either total hospital length of stay or intensive care stay, and no difference in overall mortality.

Van Hilten and colleagues[151] reported a large prospective randomized clinical study that examined infection rates among patients undergoing aortic aneurysm or gastrointestinal cancer surgery. Among 1200 patients randomized prior to transfusion, 545 were transfused. Among those transfused, the two groups were balanced between those randomized to receive leukofiltered products ($N = 237$) or nonfiltered products ($N = 257$). Among transfused patients, there was no statistical difference between leukoreduced versus nonleukoreduced groups for postoperative infection. There was also no effect of leukoreduction on the incidence of multiorgan failure or death. Median length of stay in intensive care was lower in the patients assigned to receive leukoreduced blood, but mean overall hospital length of stay was not different between the two groups.

In the largest prospective randomized trial, Dzik and coworkers[27] randomly assigned all transfused patients who did not meet standard criteria for leukoreduced blood to receive either leukofiltered components ($N = 1355$ patients) or nonleukoreduced components ($N = 1425$ patients). Patients included both surgical and medical patients with no exclusions. Any infection sufficiently severe to cause treating physicians to begin antibiotic therapy was recorded. The results showed no difference between the two groups for the proportion of patients who were treated with antibiotics after transfusion (leukoreduced = 66%; control 68%, $P = 0.42$) and showed no difference for the duration of antibiotic therapy. There was also no difference when antibiotic use was analyzed for the postoperative period among surgical patients. Subgroup analysis also found no effect of leukoreduction on the proportion of patients receiving antibiotics (or the duration of antibiotic therapy) among specific patient groups, including colorectal surgery ($N = 110$), noncardiac surgery ($N = 1087$), and nonsurgical patients ($N = 1077$). There was also no effect of leukoreduction on mortality rates or various measures of hospital length of stay.

Table 26–2 **Clinical Trials of Leukoreduction (LR) Published after the Year 2000 That Investigate Clinical Evidence for Immunosuppression and Infection**

Author	Year	Design	Patient Population	Non-LR (N)*	LR (N)*	Infection	Mortality	Length of Stay (LOS)
Tilestad et al[149]	2001	RCT	Colorectal	64	48	No effect	No effect	No effect

*Number of patients shows *transfused* patients. Several studies randomized more patients not all of whom were transfused.
†LR group had lower in-hospital rate of nonserious infections, but LR group had higher rate of infections postdischarge.
‡Infection rates declined ($p < 0.05$) when switched from LR to non-LR.
§Unadjusted odds ratio for mortality significantly lower for LR group, but significance not found when odds ratio adjusted for effect of cardiac medications.

CARDIAC SURGERY

Interest in a possible beneficial effect of leukocyte reduction more specific for cardiac surgery patients originated from the early report of van de Watering and colleagues.[152] They randomly assigned more than 900 patients undergoing cardiac surgery to three groups. Among those transfused, patients received either prestorage leukofiltered RBCs (N = 283), poststorage leukofiltered RBCs (N = 280), or buffy coat–depleted but not extensively leukoreduced RBCs (N = 303). The primary outcome of the study was infection complications, and the authors found no effect of leukoreduction on the frequency of infection outcomes (P = 0.15). An unexpected finding was a lower 60-day mortality (3.5%) in either of the leukofiltered arms compared with the nonleukoreduced blood arm (7.9%); P = 0.025. Although van de Watering found no evidence that transfusion increased the rate of postoperative infection, the authors noted that the difference in mortality was only apparent among patients receiving more than 3 units of RBCs and appeared to be due to different rates of wound dehiscence or multiorgan failure.

Three prospective randomized trials published since 2000 examined infection rates and mortality among cardiac surgery patients. Wallis and associates[153] reported results among 510 transfused patients assigned to receive control RBCs (N = 163); buffy coat–depleted RBCs (N = 173), or leukofiltered RBCs (N = 174). Although patients were randomized prior to transfusion, significantly fewer patients assigned to receive control RBCs were transfused. Among transfused patients, they found that use of control RBCs was associated with more events coded as infection (P = 0.02). However, when events coded as urinary tract infection were excluded, there was no significant difference among the three groups; P = 0.25. Following discharge from hospital, a significantly higher rate of infection requiring antibiotic treatment was found among patients assigned to receive leukoreduced blood (47%) compared with control RBCs (34%); P = 0.01. The authors concluded that no evidence was found that leukocyte reduction reduced postsurgical infection rates.

Bilgin and colleagues[154] conducted a second clinical trial in cardiac surgery focusing on patients undergoing valve-replacement surgery (with or without bypass grafting). Patients were randomly assigned to receive either buffy coat–depleted RBCs (N = 216) or leukofiltered RBCs (N = 216). Multiple outcomes were compared with no statistical correction for multiple comparisons. Among transfused patients, infection rates were higher in patients assigned to buffy coat–depleted blood (mean odds ratio = 1.64; 95% CI, 1.08–2.49). However, in-hospital mortality, frequency of multiorgan failure, length of stay in intensive care, overall length of stay in hospital, or 90-day mortality were all not significantly different between the two groups.

Bracey and co-workers conducted a prospective randomized trial in cardiac surgery patients at the Texas Heart Institute.[155] Patients were randomized prior to transfusion. Transfused patients assigned to receive control blood components (N = 159) or leukoreduced RBCs (N = 136) were balanced for preoperative risk factors, surgical procedures, and dose of transfusion. The authors found no difference in the two groups for in-hospital infections or infections during the first 3 months after discharge. There was also no difference in the two groups for mortality, intensive care length of stay, or overall hospital length of stay.

The prospective trial of Dzik and colleagues[27] included all patients undergoing cardiac surgery during the study period. Patients (N = 246) received transfusion with leukoreduced blood compared with patients (N = 260) who received nonleukoreduced components. Infection rates, measured by the clinical decision to administer antibiotic therapy, were not different in the two groups.

In addition to the above randomized trials, four studies in cardiac surgery patients examined outcomes among a cohort of patients transfused before implementation of leukoreduction compared with outcomes in a subsequent cohort of patients transfused after implementation of leukoreduction.

Volkova and associates[156] reported a study based on three sequential cohorts of patients: those receiving nonleukoreduced blood (N = 416), then a cohort receiving transfusion following implementation of leukocyte-reduced blood (N = 484), and finally a cohort transfused following return to the use of nonleukocyte-reduced blood (N = 317). They noted that mean hospital length of stay decreased progressively with each subsequent time interval (15.9 days, 14.1 days, and 12.1 days). Thus, the implementation of leukoreduction in 1992 was associated with a reduced length of stay, but the discontinuation of leukoreduction and a return to nonleukoreduced blood was also associated with a further decreased length of stay. This finding suggests that hospital length of stay was simply decreasing independently of blood policy and demonstrates that "before-versus-after" study designs can produce misleading conclusions. Observed rates of infection were not reduced with implementation of leukocyte reduction but declined in the third cohort after the switch from leukoreduced to nonleukoreduced blood.

In the study by Fung and colleagues[157] 501 patients received unfiltered blood products.[158] The following year, 645 patients received leukofiltered products. No significant changes were seen in the rate of mediastinitis, operative mortality, or stay in intensive care. There was a statistically significant decrease in postoperative hospital length of stay. This study also did not identify an immunosuppressive effect of donor leukocytes as measured by infection rates.

Llewelyn and colleagues[159] reported outcomes among cardiac surgery and orthopedic surgery patients in 11 hospitals before implementation of leukoreduction (N = 997) and compared these to outcomes following implementation (N = 1098). The proportion of all transfused patients with suspected or proved infection was unchanged before and after implementation of leukoreduction (odds ratio 0.83; 95% CI, 0.77–1.02). Among cardiac patients, use of leukoreduced blood was statistically associated with a *higher* rate of proved infections (P = 0.004). Overall postoperative length of stay was also not affected by leukoreduction. Subgroup analysis showed no effect related to dose of blood transfused. Mortality rates among cardiac surgery patients were increased following implementation of leukocyte reduction (P = 0.031) but were decreased among orthopedic patients. The authors concluded that leukoreduction did not improve outcomes.

The large Canadian study that examined outcomes before versus after implementation of leukoreduction included cardiac patients.[26] Patients in cohort 1 (N = 4475) were transfused with nonleukoreduced blood, and those in cohort 2 (N = 5050) received leukoreduced blood. There was no effect of leukoreduction on the adjusted odds of death and no observed effect of leukoreduction on infectious complications.

Taken together, the findings of clinical studies in surgery patients since 2000 fail to demonstrate that leukocyte reduction has any significant or consistent effect on the incidence of postoperative infection. Whether allogeneic transfusion by itself (with or without donor leukocytes) causes an immunosuppression not seen in untransfused individuals is not resolved by these studies. However, the finding that leukoreduction fails to change infection outcomes argues against a role for donor leukocytes in any proposed immunosuppressive effect on bacterial defenses. The studies provide conflicting results regarding overall hospital length of stay among cardiac patients assigned to receive leukoreduced blood components, and the extent to which any findings can be attributed to leukoreduction (especially in before-versus-after study designs) is difficult to determine. The early observation by van de Watering of decreased mortality in a subgroup of cardiac valve patients receiving leukoreduced blood compared with nonleukoreduced blood was not substantiated in any subsequent study. In summary, the clinical trials data since the year 2000 suggest that transfusion-related immunosuppression, if it does exist, may be mediated by factors other than donor leukocytes.

ADVERSE REACTION TO FILTRATION AND LEUKOCYTE REDUCED COMPONENTS

Administration of leukocyte-reduced components is generally safe with a few adverse effects. Now, when the process of leukoreduction occurs mostly during, or shortly after, component collection, the profile of adverse reactions has changed. When bedside leukoreduction was commonplace, the main observed adverse reaction was hypotensive episodes due to bradykinin production upon activation of the contact phase. With the increased use of prestorage leukoreduced components, this type of reaction is less likely to occur; however, the manufacturing process may now play a more important role as a cause of observed reactions. This section discusses three types of reported adverse reactions: (1) hemolysis due to leukoreduction, (2) hypotensive reactions due to contact system activation, and (3) hypotensive reactions to prestorage leukoreduced components.

Hemolysis Due to Prestorage Filtration

There has been a concern that prestorage leukoreduction may lead to an increased level of hemolysis in stored RBC components. First reports posted on transfusion medicine discussion group[160] in 2001 described increased hemolysis in segments of leukoreduced units versus nonleukoreduced units. The ensuing discussion did not identify a cause for hemolysis but raised awareness of this potential manufacturing problem. However, no adverse clinical sequelae were reported related to hemolysis. After this initial report the FDA continued to receive reports of hemolysis in RBC and WBC components following leukocyte reduction using a high-efficiency filter. Because of this information, Pall Medical decided to perform a voluntary market recall of their Leukotrap SC RC.[161] Additional units were recalled in February 2005. The hemolysis has been reported both immediately following filtration as well as 24 to 48 hours after leukocyte removal. The cause of this phenomenon is unclear at this time. Gyongyossy-Issa and associates[162] analyzed the influence of ambient temperature at which filters are used on the degree of hemolysis. The results supported a notion that when the leukoreduction is performed at 4° C in a strictly controlled environment, hemolysis can be avoided. Janatpour and co-workers[158] studied three different methods for determination of hemolysis in segments and the unit. They split the units into two aliquots, one of which was leukoreduced, and measured plasma hemoglobin using (1) a HemoCue Plasma/Low Hb Photometer system, (2) a tetramethyl-benzidine (TMB) chemical method, and (3) a free Hb visual comparator. They concluded that visual criteria overestimate the degree of hemolysis. Other methods could be more objective, raising the question whether a visual inspection of hemolysis can be used as the part of the quality control of the unit prior to distribution.

Although there were no reported clinical side effects of the increased hemolysis postfiltration, this scenario underscores the need for postmarketing surveillance of WBC filters and the quality of components. It remains to be seen if increased hemolysis translates into clinically detectable side effects. However, even without such adverse events, transfusion services should remain vigilant in detecting potential problems with any blood components. This proactive approach should be able to identify manufacturing problems early on and eliminate them in a timely manner.

Hypotensive Reactions to Bedside Leukoreduction

There have been several case reports of severe hypotension, occasionally accompanied by skin flushing and loss of consciousness, developing in patients who received bedside filtered blood components.[163–170] Although the reported incidence of these reactions is relatively low and is decreasing as fewer products are transfused using bedside filtration, some reactions have been severe and illustrate an interesting phenomenon. Four clinical features intersect to result in these reactions: transfusion of plasma-containing blood components; use of a bedside leukoreduction filter; use of a filter whose medium carries a net negative charge; and, most importantly, the concurrent administration of angiotensin-converting enzyme (ACE) inhibitors to the recipient. The sudden elaboration of bradykinin was a prime suspect as the cause of these reactions because bradykinin had previously been implicated in anaphylactic reactions observed among patients receiving ACE inhibitors and undergoing low-density lipoprotein apheresis or hemodialysis.[171–173]

Implication of Kinins and Activation of the Contact Pathway in the Pathogenesis of Hypotensive Reactions

Two related vasodilator peptides—the nonapeptide bradykinin and the decapeptide lysyl-bradykinin (kallidin)—exert strong hypotensive effects in humans. Both peptides are metabolized by kininase I, a carboxypeptidase that removes one amino acid (arginine) from the carboxyterminal end. Kininase II, also known as ACE, removes two amino acids (phenylalanine and arginine) from the carboxyterminal end, rendering the peptides inactive. Bradykinin and lysyl-bradykinin are formed from two precursor proteins: high-molecular-weight kininogen, or HMWK (approximately 110,000 D), and low-molecular-weight kininogen, or LMWK (approximately 68,000 D) (Fig. 26–2). The physiologic function of both

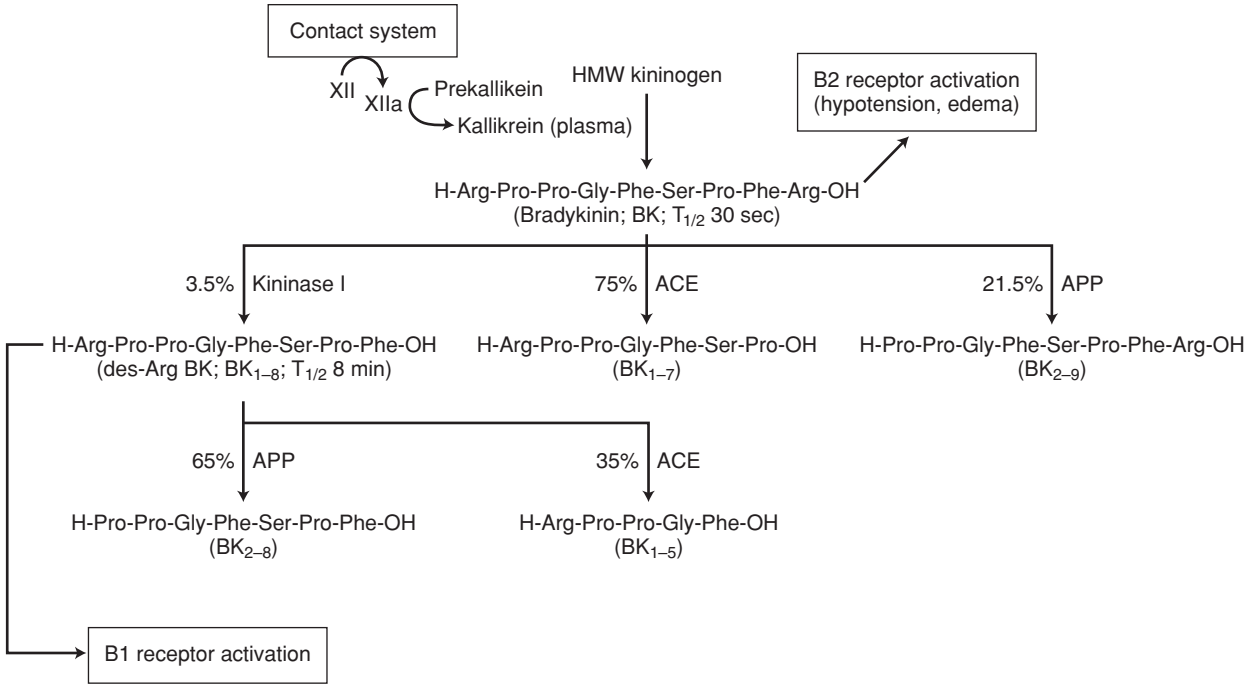

Figure 26–2 Simplified diagram representing synthesis and catabolism of bradykinin. The contact system upon activation through contact with a negatively charged surface (e.g., glass, kaolin, dextran sulfate, blood filter, dialysis membrane) leads to activation of the intrinsic coagulation cascade and to bradykinin (BK) generation. The active components of this pathway include kallikrein, bradykinin (acts through B2 receptor), and des-Arg9 bradykinin (acts through B1 receptor), all labeled in boldface. The other metabolites of bradykinin are inactive. The inhibition of the major pathway of catabolism by ACE inhibitors results in prolongation of the half-life ($T_{1/2}$) of active components and clinical signs and symptoms. ACE, angiotensin-converting enzyme; APP,. aminopeptidase; HMW, high molecular weight; LMW, low molecular weight.

kinins is exerted through their action on two receptors, B1 and B2. These receptors were cloned and identified as serpentine receptors coupled to G proteins. Because bradykinin and lysyl-bradykinin are primarily tissue hormones, their concentration in the circulation is usually low. Reported physiologic levels vary from less than 3 to 55 pg/mL.[174,175] Both peptides are responsible for contraction of visceral smooth muscles, but they relax vascular smooth muscles through the action of nitric oxide. In addition to the effect on smooth muscle cells, the kinins cause increased capillary permeability, accumulation of leukocytes, and pain after injection under the skin. Bradykinin acting on the B2 receptor triggers nitric oxide formation, which activates guanylate cyclase in smooth muscle cells, leading to increased concentrations of cyclic guanosine monophosphate (cGMP) and smooth muscle relaxation.[176] Previous studies have shown that bradykinin also activates phospholipase A_2, phospholipase C, protein kinases, and prostaglandins, thereby resulting in the accumulation of cGMP and cyclic adenosine monophosphate in cells.[177] Although bradykinin can activate tissue mast cells, leading to release of histamine,[178] histamine release does not account for the full vasodilatory effects of bradykinin. Dachman and colleagues[179] demonstrated a residual vasodilatory effect even in the presence of a $histamine_1$ receptor antagonist (brompheniramine) and a $histamine_2$ receptor antagonist (cimetidine).

In healthy individuals, approximately 95% of injected bradykinin is metabolized during the first passage through the lungs. Pulmonary kininases rapidly degrade bradykinin, thereby preventing its effect on the arterial circulation. Indeed, these pulmonary kininases may normally provide transfusion recipients with protection against bradykinin-induced vasodilation. However, pulmonary breakdown of bradykinin is significantly diminished among patients with genetically low activity of pulmonary kininases and patients receiving ACE inhibitor medications. In addition, patients undergoing cardiopulmonary bypass are at increased risk for bradykinin-mediated hypotensive reactions, because during the bypass venous blood flow is diverted around the pulmonary circulation. The largest series of severe hypotensive reactions accompanying bedside leukoreduction filtration was reported among patients undergoing cardiopulmonary bypass.[165]

The vasodilatory effect of bradykinin was studied in several experimental settings. Forearm blood flow increased after doses of 10 and 100 ng/min.[180,181] Icatibant, a B2-kinin receptor antagonist, was used to demonstrate dose-dependent vasodilation in response to bradykinin. With increased dosage of icatibant, blood flow diminished significantly. N(G)-monomethyl-L-arginine, a specific inhibitor of nitric oxide synthase, was used to demonstrate that bradykinin-induced vasodilation is mediated in part by nitric oxide.[180]

Bonner and colleagues[182] reported on the hemodynamic effects of bradykinin on the systemic and pulmonary circulation in normotensive and hypertensive subjects. Bradykinin was injected intravenously and intra-arterially at doses ranging from 42.4 to 6413 ng/kg. Bradykinin lowered blood pressure by decreasing systemic vascular resistance. ACE inhibitors potentiated this effect by approximately 20- to 50-fold. Systolic blood pressure declined by more than 20 mm Hg when the arterial bradykinin concentration reached at least 100 pg/mL. The study demonstrated that the physiologic effect of bradykinin is very rapid, with a hypotensive effect demonstrable within seconds after administration.

Activation of Contact System During Passage of Blood through Leukoreduction Filters

Because bradykinin elaboration would occur if the contact system were activated, investigators have examined whether leukofiltration could induce contact activation of blood. Studies have measured either an increase in bradykinin or its stable metabolite 1,5-bradykinin or a decrease in the substrates HMWK or LMWK. Although direct measurement of bradykinin is more appealing, bradykinin is technically difficult to assay owing to ex vivo activation of the contact system. Shiba and coworkers[183] measured bradykinin during leukofiltration of platelet concentrates, using a negatively charged filter and a positively charged filter. After filtration through the negatively charged filter, decreased levels of prekallikrein and increased levels of bradykinin were observed. The bradykinin level was inversely related to the activity of ACE in the platelet concentrates. The same group studied the effects of storage time, plasma dilution, and filtration on contact-system activation in packed RBCs preserved in mannitol-adenine phosphate solution.[184] The authors noted an increase in the bradykinin level, up to 500 pg/mL on the 10th day of storage. The level decreased to 200 pg/mL during the subsequent 5 days and remained at this low level until the end of the storage time. A significantly decreased level of ACE activity was noted in the packed RBCs stored in solutions containing mannitol. Filtration using two different negatively charged filters generated bradykinin levels up to 6000 pg/mL. The authors concluded that mannitol may act as an ACE inhibitor, slowing down catabolism of bradykinin and leading to its accumulation in stored RBCs. Hild and colleagues[185] studied generation of bradykinin during leukofiltration of platelets using three different filters—negatively charged, positively charged, and neutral. Only the negatively charged filter contributed significantly to bradykinin production. The levels of bradykinin detected in the eluate varied from less than 200 pg/mL to as much as 10,000 pg/mL in samples collected after the processing of 50 and 100 mL of platelet concentrates. The final concentration in units ranged from 200 to 2500 pg/mL. Interestingly, bradykinin present after filtration was rapidly metabolized; after 60 minutes of storage, the bradykinin level was below the limit of detection. However, when an ACE inhibitor was added to the storage bag, bradykinin levels remained elevated for as long as 90 minutes.[185] Significant differences in bradykinin production were observed among the donors, so that some components generated measurable levels of bradykinin but others did not. The highest bradykinin levels (>20,000 pg/mL) were observed after leukofiltration of apheresis platelets. Scott and associates[186] investigated bradykinin generation by negatively charged filters by measuring substrates of the contact system during leukoreduction of apheresis platelets. The number of WBCs before leukoreduction varied from 0.5 to 1000 cells/μL. Two different leukocyte filters were used. Measurements of the cleavage products of HMWK and LMWK were used as markers of contact-phase activation and the potential for bradykinin production. Although no significant changes were detected in kininogen cleavage products, the assay could not exclude conversion of small amounts (<5%) of kininogen to kinin. The authors concluded that clinically significant activation of the contact system did not occur as a result of leukofiltration. However, they did observe a temporary decrease in kininogen levels with one of the studied filters. The interpretation of this study is difficult because, on a molar basis, kininogen is a very abundant molecule. Therefore, conversion of a minor fraction of kininogen could result in very significant levels of bradykinin.

Why is it that not all patients react uniformly when given bedside transfusions while receiving ACE inhibitors? Cyr and colleagues[187] studied the influence of ACE inhibitor medication on the in vitro generation of bradykinin and its active metabolite des-Arg9-bradykinin. The in vitro half-life of bradykinin and of des-Arg9-bradykinin was measured in the presence of an ACE inhibitor in serum from four patients who had experienced hypotensive reactions during blood transfusions of leukoreduced products. Although the half-life of bradykinin did not differ between the patients and controls, the degradation of des-Arg9-bradykinin was significantly slower in the patient samples (1549 vs 661 seconds). The authors proposed the hypothesis that an anomalous metabolism of des-Arg9-bradykinin might contribute to selection of patients who experience clinical reactions to bedside leukodepletion.

On the basis of the published studies, bradykinin produced during bedside filtration of platelets seems to be responsible for reactions during bedside leukofiltration in patients taking ACE inhibitor medications. Reactions to RBC components may be less likely, because cold storage of RBCs inhibits contact activation enzymes and because RBCs contain less plasma and kininogens. Concern regarding hypotensive reactions among patients receiving blood components filtered at the bedside prompted the FDA to issue a letter to physicians in May 1999. The FDA recommended use of blood products leukoreduced at the time of collection or during laboratory storage whenever available.

Hypotensive Reactions to Prestorage Leukoreduced Components

Arnold and colleagues[188] report two patients who developed hypotensive reactions after receiving prestorage leukoreduced components. Both patients were taking ACE inhibitors. This observation puts in question the assumption (as discussed above) that only bedside filters can activate the contact system to a sufficient degree to cause bradykinin generation with subsequent development of hypotension. A hypothesis was put forward that the ACE inhibitors present during the collection of the autologous (or allogeneic) unit were responsible for bradykinin accumulation during leukodepletion. This hypothesis would require significant contact phase activation with significant accumulation of bradykinin. Additional studies are needed to answer this question.

Similar reactions have been observed and reported in the patients undergoing therapeutic plasmapheresis, even if the replacement fluid consisted only of 5% albumin, though it was more common to observe such reaction with fresh frozen plasma. Owen and Brecher[189] performed a retrospective study to identify all patients who developed "atypical reactions" while undergoing therapeutic plasma exchange over the course of 12 years. The authors concluded that the use of ACE inhibitors was associated with symptomatic hypotension during the procedure and recommended that ACE inhibitors be discontinued at least 24 hours prior to apheresis procedure. Thus, it seems plausible that the patients undergoing therapeutic plasmapheresis with albumin as a replacement fluid are at increased risk for hypotension if concomitantly on ACE inhibitors.[189–192]

Chapter 27

Virus-Safe Products: Pathogen Reduction and Inactivation

Laurence Corash

INTRODUCTION

Transfusion of blood components continues to be implicated in transmission of viral, bacterial, and protozoan diseases,[1] and the landscape of these infections and technologies to inactivate contaminating pathogens has continued to evolve. This review focuses on technologies that have reached the clinical trial phase. In the past 5 years, threats to blood safety from the emergence of new pathogens, migration of donor populations from regions with unusual endemic infectious agents, and increased recognition of problems in averting transfusion of labile components contaminated with recognized pathogens continue to emphasize the need for robust pathogen inactivation technologies. Since the previous edition of this text, new technologies for the prevention of transfusion-transmitted infections have been introduced into clinical practice, providing an opportunity to assess the practical efficacy of these technologies.

The residual risk for human immunodeficiency virus (HIV) and hepatitis C virus (HCV) transmission by transfusion varies by geographic region.[2] Continued improvements in donor screening with the introduction of nucleic acid testing (NAT) have decreased the risks for HIV and HCV to very low levels, ranging from 1:400,000 to 1:5,540,000 per donation.[3,4] However, greater risks remain for hepatitis B virus (HBV), ranging from 1:102,000 to 1:220,000,[3,5] and in some regions NAT has failed to detect significant numbers of donations with low levels of virus.[6] Although the risks per donation for HIV and HCV have diminished substantially with NAT, it is important to recall that many patients receive multiple transfusions for support of intensive therapies, and the residual risk of transfusion-transmitted infection increases with the number of donor exposures.

While it is commonly recognized that HIV, HCV, HBV, cytomegalovirus (CMV), and human T-lymphotropic viruses (HTLV) can be transmitted through cellular components, other pathogens are also emerging as potentially significant transfusion-associated infectious agents.[7] For example, transmission of protozoan infections due to trypanosomes,[8–10] *Leishmania*,[11] and *Babesia* have been documented.[12] Although protozoan agents have typically been thought of as unimportant transfusion-associated infections, recent experience with *Babesia* indicates seroprevalence rates among blood donors as high as 4%.[13]

Over the past 5 years, experience with conventional methods to prevent transfusion-associated transmission of infectious pathogens has demonstrated the continuing need for technologies to further improve the safety of blood transfusion.[14] The West Nile virus epidemic illustrates the limitations of testing as a reactive strategy to prevent transfusion transmission of an emerging pathogen.[15] Despite the rapid deployment of a sensitive test to detect infected blood donors, not all cases can be prevented owing to low copy numbers of virus in some infectious donors.[16,17] In addition, other viruses with early-phase low viral burdens may escape detection by sensitive methods.[18] For cell-associated viruses such as CMV and HTLV, leukoreduction technologies may be inadequate to ensure compete removal of infected cells as demonstrated by both in vitro[19,20] and in vivo studies.[21]

With the introduction of widespread culturing of platelet components to detect bacteria, the data indicate a prevalence greater than previously expected.[22] Within the last 5 years four studies have reported experience with culturing approximately 200,000 platelet components. The rates of contamination have ranged from 0.3% to 0.7% (3–7 per 1000 units) depending on volume cultured and use of both aerobic and anaerobic cultures.[23–26] More importantly, these studies demonstrated that the majority of the contaminated components were not interdicted before transfusion. Reported cases of serious transfusion-transmitted sepsis are infrequent and are generally due to highly contaminated units.[27] However, the true prevalence of platelet transfusion-transmitted infections encompassing all clinical consequences remains unknown.[22] Only one prospective study of 3584 platelet transfusions in 161 bone marrow transplant patients has been conducted and demonstrated a risk of symptomatic bacteremia in 1 per 16 patients, 1 per 350 transfusions, and 1 per 2100 platelet units.[28] These frequencies are significant considering that over 8 million units of platelet concentrates are transfused annually in the United States alone.[29] Despite the implementation in 2004 of requirements for bacterial detection of platelet components in the United States, at least three deaths due to transfusion of contaminated platelet components have been reported to the CDC.[30]

The logistics and costs of continued expansion of testing processes—for example, NAT and bacterial cultures—to further improve blood safety have been questioned.[23,31,32] The impact of bacterial detection methods has delayed release of platelet units and shortened the effective shelf life, leading to increased rates of expiration.[33] Furthermore, testing remains a reactive strategy to ensure blood component safety, since new pathogens may enter the donor population before adequate tests can be implemented. A complementary approach to improving the safety of blood component transfusion is

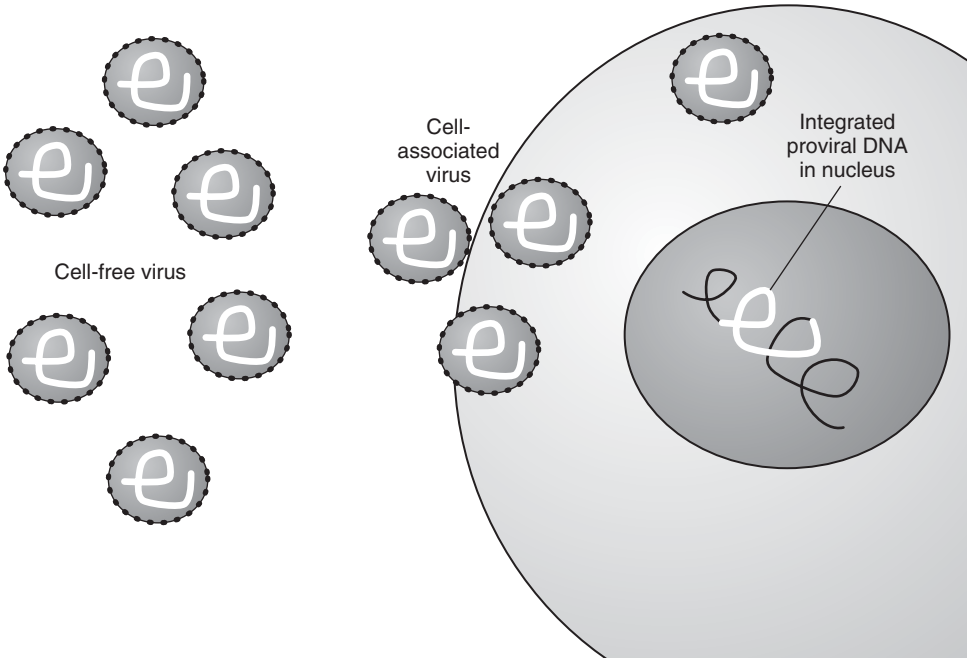

Figure 27–1 Infectious pathogens (e.g., viruses) may be present in the plasma as cell-free virus, associated with cell membranes, in the cell cytoplasm, or in the nucleus. Moreover, some viruses (e.g., retroviruses) may integrate nucleic acid sequences into host genomic DNA. A robust pathogen inactivation technology should be effective in each of these compartments.

inactivation of infectious pathogens in blood components. Treatment of plasma fractions with the solvent detergent process has demonstrated the benefits of this approach.[34] A robust inactivation technology that is compatible with current blood component processing procedures offers the potential for significantly improving transfusion safety. To be highly effective, a successful technology must inactivate pathogens in extracellular, intracellular, and nuclear compartments (Fig. 27–1). In the last case, inactivation also must be effective against pathogen nucleic acid sequences integrated into donor leukocytes.

Furthermore, a technology capable of inactivating residual leukocytes may confer additional benefits owing to inhibition of critical leukocyte functions, including cytokine synthesis, lymphocyte proliferation, and antigen presentation. Donor leukocytes may be associated with a variety of adverse immune events ranging in severity from febrile transfusion reactions to alloimmunization and graft-versus-host disease.[35,36] Recently, studies have shown that massively transfused patients may develop stable microchimerism, the significance of which is unclear.[37] Although a number of measures have been implemented to reduce the likelihood of these adverse immune reactions, a robust nucleic acid targeted pathogen inactivation process offers the potential to inactivate leukocytes as well as infectious pathogens.

SYSTEMS FOR INACTIVATION OF PATHOGENS IN PLATELET CONCENTRATES

Considerable effort has been devoted to developing methods for pathogen inactivation in platelet concentrates (Tables 27–1 and 27–2). The potential processes are divided into two basic groups: nucleic acid targeted and photodynamic methods. Both methods utilize photochemical reactions in an ex vivo treatment process combining a photo reactive compound and ultraviolet (UV) light. Nucleic acid targeting using psoralen compounds has been extensively investigated and is discussed in detail below, since a method using the novel psoralen amotosalen has undergone clinical trials and been commercialized. The photodynamic methods generally result in lower levels of pathogen inactivation and are associated with more platelet injury.[38] These technologies will not be reviewed further (see Table 27–2), with the exception of the riboflavin method, which has advanced to clinical trials.

The psoralen-based methods generally rely on nucleic acid–specific adduct formation,[39] in contrast to photodynamic processes that tend to utilize the production of active oxygen species in addition to nucleic acid reactions as the primary mechanism for pathogen inactivation.[40] Psoralens are low-molecular-weight, planar furocoumarins (Fig. 27–2). In the absence of UV light, psoralens reversibly intercalate into helical regions of DNA and RNA, under equilibrium kinetics. Upon illumination with UVA (320 to 400 nm), psoralens react with pyrimidine bases to form covalent mono-adducts and cross-links with nucleic acids (Fig. 27–3). Bacteria,[41] protozoa,[42,43] viruses,[44] and nucleated cells[45] with genomes that have been modified by psoralens are unable to replicate.

Early investigations with psoralen-mediated pathogen inactivation were conducted with 8-methxyopsoralen (8-MOP)[46] based on the history of prior human use to treat psoriasis and cutaneous T-cell lymphoma. These initial studies by Lin and co-workers established the principle of psoralen-mediated pathogen inactivation, but 8-MOP photochemical treatment was not a sufficiently rapid process for treatment of platelet concentrates in clinical use.[46,47]

Table 27–1 Psoralen Methods Used to Inactivate Pathogens and Leukocytes in Platelet Concentrates

Photoreactive Agent	Target	Reference
8-MOP	fd, R17, FeLV, *Escherichia coli, Staphylococcus aureus*	46
8-MOP	MCMV, FeRTV	132
8-MOP	HIV	133
8-MOP	DHBV	134
8-MOP	12 pathogenic bacteria	135
AMT	VSV	136
AMT	HIV	137, 138
AMT	VSV, Sindbis	139
PSR-Br	Bacteriophage	140, 141
Amotosalen	Pathogenic bacteria	67
Amotosalen	Leukocytes	45
Amotosalen	HIV, DHBV, BVDV	67
	CMV, bacteria	41, 44

8-MOP, 8-methoxypsoralen; AMT, aminomethyltrimethyl psoralen; PSR-Br, brominated psoralens; fd, bacteriophage; R17, bacteriophage; FeLV, feline leukemia virus; MCMV, murine cytomegalovirus; FeRTV, feline rhinotracheitis virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; DHBV, duck hepatitis B virus; VSV, vesicular stomatitis virus; Sindbis, Sindbis virus; BVDV, bovine viral diarrhea virus; CMV, cytomegalovirus.

Two laboratories investigated the use of aminomethyltrimethylpsoralen (AMT), a synthetic psoralen with enhanced nucleic acid–binding efficiency (see Table 27–2). Although AMT has increased nucleic acid–binding affinity compared with 8-MOP, it exhibits mutagenicity in the absence of light and thus has an unfavorable toxicology profile. Several classes of new psoralens have been synthesized that offer potential advantages over AMT and 8-MOP. The halogenated psoralens do not appear to be sufficiently effective for viral inactivation and in preliminary studies demonstrated adverse effects on platelet viability.[48,49]

Table 27–2 Photodynamic Methods Used to Inactivate Pathogens in Platelet Concentrates

Photoreactive Agent	Target	Reference
UVB	Poliovirus	142
Merocyanine 540	VSV	143
Merocyanine 540	HSV, MS2, F6	136
Methylene blue	Unspecified	144
Phthalocyanines	VSV	145
Riboflavin	HIV, WNV, PPV	55

UVB, ultraviolet B light (280–320 nm; VSV, vesicular stomatitis virus; HSV, herpes simplex virus; MS2, bacteriophage; F6, bacteriophage; HIV, human immunodeficiency virus; WNV, West Nile virus; PPV, postpolio virus.

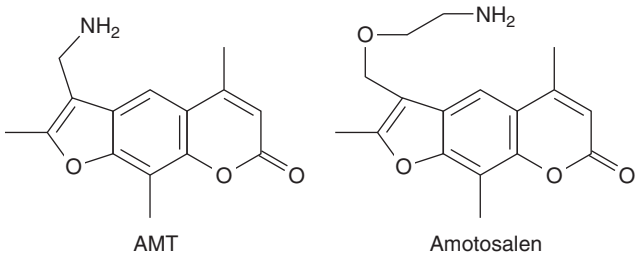

Figure 27–2 Structures of aminomethyltrimethylpsoralen (AMT) and amotosalen.

A new amino psoralen, amotosalen, was synthesized and shown to be highly effective for inactivation of pathogenic viruses, bacteria, and leukocytes in platelet concentrates with preservation of in vitro platelet function properties (Table 27–3). Lin and co-workers reported that human platelet concentrates (300 mL) contaminated with high titers of HCV($10^{4.5}$) and HBV($10^{5.5}$) and treated with amotosalen did not transmit hepatitis after transfusion into naive chimpanzees. Jordan and colleagues have shown that amotosalen treatment effectively prevents transfusion-transmitted CMV infection in a sensitive murine model.[50] Other studies demonstrated that amotosalen inactivates high levels of T cells, inhibits leukocyte cytokine synthesis during platelet storage, and inhibits nucleic acid amplification.[45,51] More importantly, treatment of T cells with the amotosalen process prevented transfusion-associated graft-versus-host disease (TA-GVHD) in both immunocompetent and immunocompromised murine bone marrow transplant models.[52] Amotosalen treatment of platelet concentrates

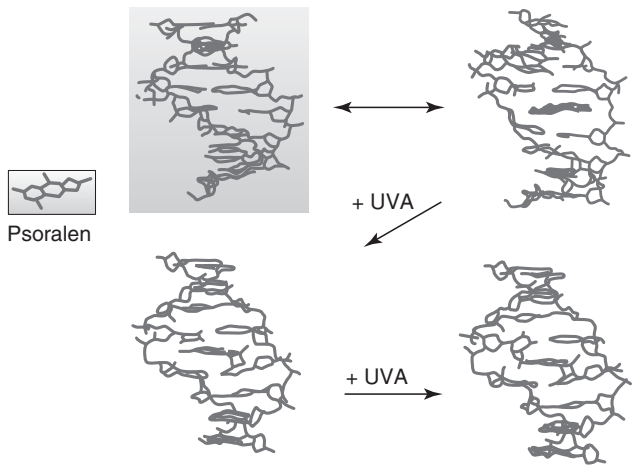

Figure 27–3 The mechanism of amotosalen binding to nucleic acid. In the dark, psoralens intercalate into helical regions of nucleic acid, either DNA or RNA. This phase is a reversible equilibrium process without covalent addition to nucleic acid. During illumination with long wavelength ultraviolet light (UVA), mono-adducts and di-adducts between amotosalen and pyrimidine form. Both types of adducts inhibit the function of polymerases and block nucleic acid replication.

Table 27–3 Summary of Amotosalen Pathogen Inactivation in Platelet Concentrates

Pathogen	Strain	Inactivation Achieved
HIV-1	IIIB, cell-free	$>10^{6.2}$ pfu/mL
	IIIB, cell-associated	$>10^{6.1}$ pfu/mL
	Integrated provirus*	No p24 expression using 0.1 μM Amotosalen + 1 J/cm^2
	Clinical isolate Z84, cell-free†	$>10^{3.4}$ TCID50/mL
HIV-2	Clinical isolate CBL20, cell-free†	$>10^{2.5}$ TCID50/mL

	Staphylococcus aureus	$10^{6.6}$ cfu per unit
	Escherichia coli	$>10^{6.4}$ cfu per unit
	Yersinia enterocolitica	$>10^{5.9}$ cfu/mL
	Serratia marcescens	$>10^{6.7}$ cfu per unit
	Salmonella choleraesuis	$>10^{6.2}$ cfu/mL
	Enterobacter cloacae	$10^{5.9}$ cfu/mL
	Klebsiella pneumoniae	$>10^{5.6}$ cfu per unit
	Pseudomonas aeruginosa	$10^{4.5}$ cfu/mL
	Bacillus cereus	$>10^{3.6}$, $\leq 10^{3.9}$ cfu per unit

HIV, human immunodeficiency virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HCMV, human cytomegalovirus, DHBV, duck hepatitis B virus; BVDV, bovine viral diarrhea virus, MCMV, murine cytomegalovirus; pfu, plaque-forming units; ID_{50} infectious dose which is measured from an endpoint dilution that causes infection in 50% of inoculated animals; cfu, colony-forming units; $TCID_{50}$, tissue culture infectious dose, which is measured from an endpoint dilution that causes infection in 50% of inoculated samples; CID_{50}, chimpanzee infectious dose, which is measured from an endpoint dilution that causes infection in 50% of inoculated chimpanzees.

* Three studies are indicated: the HIV-1 provirus inactivation was performed in cell culture medium and the other two studies were performed with platelet sample size less than 300 mL.

†Highest titers possible.

‡The infectivity of the MS-2 strain of HBV and the Hutchinson strain of HCV was measured in susceptible chimpanzees.

effectively blocks PCR mediated amplification of mitochondrial DNA sequences without impairment of ATP levels.[53,54]

A photochemical treatment process using riboflavin (Fig. 27–4) and a combination of UVB and UVA light (5 J/cm^2: 265–370 nm) has been developed for platelet components suspended in donor plasma without the use of a platelet additive solution.[55] Photodynamic reactions involving the generation of active oxygen species are a critical aspect of riboflavin pathogen inactivation mechanism.[40] Earlier studies had used this process with additive solutions, but the system evaluated in clinical trials requires suspension of platelets in 100% donor plasma.[56] This process has demonstrated activity against enveloped viruses, a nonenveloped model virus, and two species of bacteria.[55] Earlier studies showed capacity for the inactivation of protozoa.[57] In vitro aspects of platelet function and hemostatic function assessed in an ex vivo system have shown conservation of function after riboflavin treatment.[58] The process appears to produce comparable effects on in vitro platelet properties for apheresis and pooled buffy coat platelet components.[59] Recently, preliminary data were reported describing the inactivation of lymphocytes using a murine immunodeficiency model.[60]

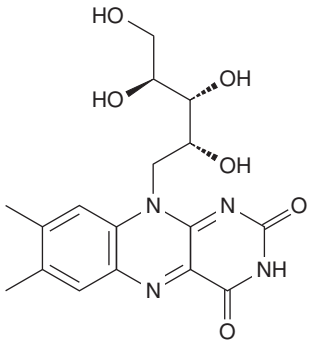

Figure 27–4 Structure of riboflavin (vitamin B_2).

Clinical Experience with Platelets Prepared with Amotosalen Photochemical Treatment

Amotosalen, formerly known as S-59, treatment of platelet components has been extensively evaluated in clinical trials[61–64] and has been introduced into practice in Europe.[65] The prototype system is a closed system with a series of plastic containers that are carried through a sequence of processing steps (Fig. 27–5). A pooled buffy-coat or single-donor platelet concentrate, suspended in approximately 35% plasma and 65% platelet additive solution, is connected to a container of amotosalen. The platelet concentrate is passed through the amotosalen container into a PL 2410 Plastic

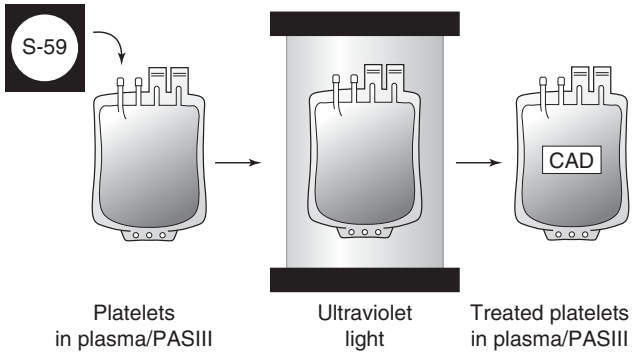

Figure 27–5 The amotosalen process for treatment of platelet concentrates. In a series of connected containers, amotosalen is added to the platelet concentrate suspended in approximately 300 mL of 35% plasma and 65% of a platelet additive solution (PAS III, Intersol). The platelet concentrate is illuminated with a 3 J/cm^2 treatment for approximately 3 minutes. After illumination, the platelet concentrate is transferred to another plastic container containing the compound absorption device (CAD). Platelets are incubated with shaking in the CAD for at least 4 hours to lower the levels of residual amotosalen and free photoproducts, followed by transfer to a final plastic container for 5 to 7 days of storage at 20–24°C. The final transfused dose of residual amotosalen ranges from 25 to 50 µg per 300 mL of platelet concentrate.

container (Baxter Healthcare Corp., Round Lake, Ill.). The platelet concentrate containing amotosalen (150 µmol/L) is illuminated with long wavelength UVA light for 3 minutes (3 J/cm^2 treatment) with reciprocal shaking at 20 °C to 24 °C in a microprocessor controlled light source. After illumination, the platelets are transferred to a compound absorption device (CAD) to passively reduce the residual amotosalen to low levels (<0.5 µmol/L). The CAD consists of resin beads integrated into PL 2410 Plastic. After CAD exposure for a minimum of 4 hours, the platelets are transferred to a final PL 2410 Plastic container for storage for 5 to 7 days under conventional platelet storage conditions with reciprocal shaking at 20°C to 24 °C.

Phase 1 and 2 studies with amotosalen-treated, 5-day-old platelets transfused in healthy subjects have shown adequate viability.[63] The average post-transfusion recovery of 5-day-old treated platelets was 42.5% with an average life span of 4.8 days. Interestingly, the rate of radiolabel elution from treated platelets was greater than that of control platelets (3.3% vs 2.1%). In these studies, treated platelets were well tolerated during and after transfusion of full therapeutic doses (300 mL, 3.0×10^{11} platelets) in healthy subjects. This study also provided information regarding the peak plasma amotosalen concentrations after transfusion and the kinetics of amotosalen clearance, including the area under the curve (AUC) and terminal half-life. The median peak amotosalen plasma level was less than 1 ng/mL and rapidly fell to concentrations below the limits of quantitative measurement.

A clinical trial was conducted to evaluate the hemostatic therapeutic efficacy of amotosalen-treated platelet concentrates and to expand the safety experience in a spectrum of patients requiring platelet transfusion support.[66] In this randomized, double-blinded crossover trial, patients received double-dose transfusions (>6.0×10^{11} platelets) of amotosalen-treated platelets and standard platelets in random order. Based on the daily platelet count, platelet transfusions were ordered by physicians blinded to the type of platelet product. Platelet counts and cutaneous template bleeding times were performed prior to each platelet transfusion, and 1 and 24 hours following each study platelet transfusion. In addition, secondary end points included clinical hemostasis before and after transfusion, the frequency of transfusion reactions, corrected count increments, and adverse events. Prior to platelet transfusion, the average platelet count was less than 13×10^9/L and the median bleeding time was greater than 30 minutes. After transfusion of amotosalen-treated platelets, the average platelet count increased to 53.2×10^9/L and the median bleeding time decreased to 15 minutes. Control platelet transfusions demonstrated an average posttransfusion platelet count of 63.3×10^9/L with a median bleeding time of 12 minutes. The improvements in bleeding times persisted for up to 24 hours after platelet transfusion. The amotosalen-treated platelets were well tolerated.

A randomized, controlled, double-blinded clinical trial was initiated using pooled whole-blood buffy coat platelets stored up to 5 days after preparation with amotosalen treatment or by conventional methods using either plasma or a mixture of plasma and an approved additive solution (T-Sol; Baxter, La Chatre, France) as the suspension medium.[62] This study enrolled 103 patients at four European centers. The experimental platelet concentrates were pooled, treated with amotosalen, and then stored for up to 5 days before transfusion. Patients were randomized to receive all platelet transfusions of the assigned type for up to 8 weeks of transfusion support with an additional 4-week period of surveillance for adverse events. The primary endpoint of this trial was the corrected count increment (CCI) 1 hour following platelet transfusion. Secondary end points included the CCI 24 hours after transfusion, clinical hemostasis, the frequency of platelet transfusion, the frequency of acute transfusion reactions, the frequency of refractoriness to platelet transfusion, the frequency of platelet associated bacteremia, and overall safety.

The average dose of experimental platelets was significantly lower than that of conventional platelets (3.9×10^{11} vs 4.3×10^{11}, $P < 0.001$). This study demonstrated that for up to the first eight transfusions the mean 1-hour CCI was not different between treatment groups (13,400 ± 5400 vs 14,900 ± 6,200, $P = 0.11$). When analyzed by linear regression using 1-hour count increments and transfused dose for all transfusions, equal doses of treated and conventional platelets did not differ significantly with respect to 1-hour post-transfusion count increments (mean difference = 1.5×10^9/L: 95% CI: -3.1 to 6.1×10^9/L, $P = 0.53$).

For up to the first eight transfusions, the 24-hour CCI results were statistically lower for treated platelets (7400 ± 5500 vs 10,600 ± 7100, $P = 0.02$). However, when analyzed by linear regression using 24-hour count increments for all transfusions, equal doses of treated and conventional platelets were not different (mean difference = 2.6×10^9/L: 95% CI: -1.3 to 6.5×10^9/L, $P = 0.19$). The mean interval between transfusions was not different between treatment groups (3.0 ± 1.2 vs 3.4 ± 1.2 days, $P = 0.13$). The treatment groups were not different with respect to hemostasis, alloimmunization, or safety.

A second clinical trial was conducted to compare the therapeutic efficacy and safety of amotosalen-treated apheresis platelets with conventional platelets.[61] This study utilized a noninferiority design to evaluate specifically the hemostatic efficacy of platelets treated with a photochemical (PCT) pathogen inactivation process in comparison to conventional platelets. It was a controlled, double-blinded trial in which 645 patients were transfused at 12 clinical centers. Single-donor platelets were collected on the Amicus cell separator system

and prepared with either photochemical treatment[41,44,67] or conventional methods. Patients were randomized to receive all platelet transfusion support of the assigned treatment type for up to 4 weeks. Patients who required additional platelet transfusion support after the initial 4-week period were invited to enroll into a second transfusion cycle for up to 4 weeks. The primary end point of this trial was the frequency of grade 2 bleeding (WHO scoring system[68]) in the two treatment groups. Grade 2 bleeding was selected as the primary end point, since it is primarily a reflection of platelet function in transfusion-dependent thrombocytopenic patients.[69–72] Secondary end points included grade 3 and 4 bleeding, time to the first grade 2 bleeding event, days of grade 2 bleeding, 1- and 24-hour platelet count increments, the interval between platelet transfusions, the frequency of acute transfusions reactions, the frequency of platelet associated bacterial sepsis, the rate of refractoriness to platelet transfusion, the number of platelet transfusions and red cell transfusions, and safety.

Analysis of data from this study showed that the incidence of grade 2 bleeding and higher grade bleeding (grade 3 and 4) was equivalent for patients supported with treated platelets and conventional platelets.[61] The median time to the first grade 2 bleeding event was 8 days and not different between the treatment groups.[61] The mean 1-hour and 24-hour CCI values were significantly lower for patients in the experimental group. Using longitudinal linear regression analysis, when equal doses of PCT and control platelets were transfused, the 1-hour post-transfusion count was estimated to be 10.4×10^9/L lower and the average time to the next transfusion was 0.4 days shorter for treated platelets. The average 1-hour increment, 24-hour count increment, and interval to the next transfusion for amotosalen-treated platelets were similar to those observed for conventional platelets in the TRAP trial.[73]

The mean number of platelet transfusions required per patient was greater for the PCT group compared with the control group; however, owing to processing and sampling losses the proportion of platelet doses below 3.0×10^{11} was significantly greater for the PCT group (20% vs 12%, $P < 0.01$).[61] Subsequently, a poststudy analysis to examine in greater detail the effect of platelet dose consistency on the number of platelet transfusions and bleeding was performed.[74] This analysis showed that when patients were transfused with all doses containing $>3.0 \times 10^{11}$ platelets of either PCT or conventional platelets, the number of platelet transfusions required for support was not different between the PCT and control groups. Similarly, when patients transfused with one or more doses of either PCT or control platelets were compared, the number of platelet transfusions required for support remained similar between the groups. Despite the differences in numbers of transfusions required, the count increments and transfusion intervals for PCT platelets were, respectively, lower and shorter for PCT platelets consistent with qualitative differences observed in phase 1 studies of platelet viability.[63]

Because the initial clinical trials were conducted with a prototype processing set that resulted in poor control of platelet doses, a study with an optimized integrated processing set configuration was carried out.[75] This was a smaller randomized controlled trial than the prior studies in which the trend for lower count increments and shorter transfusion intervals with PCT platelets persisted; however, more transfusions of PCT platelet components were not required for support of patients compared with conventional platelets.[75] With the introduction of PCT platelets into routine clinical use in Europe as of 2003, experience has been extended to examine the impact of the PCT process on platelet utilization and donor resources in a broader patient population and under routine operating conditions.[65] Preliminary reports of these studies with apheresis platelets have shown a minimal or only modest impact on platelet utilization.

Another important aspect of the use of platelet products prepared with pathogen inactivation methods has been to evaluate the safety profile of these products including the potential for induction of antibody responses to potential neoantigens. Reports of clinical trials conducted with platelets treated with amotosalen and UVA light have indicated that the safety profile of the treated platelets is similar to that of conventional platelets.[61,62,76] The cumulative experience in these trials has involved 412 patients transfused with 3736 doses of PCT platelets.[77] While differences in some specific adverse events have been observed,[76] no consistent differences or trends in system organ class adverse events were detected. Patients enrolled in the phase 3 clinical trials were primarily recruited from populations with hematologic and oncologic disorders associated with high morbidity and mortality rates and treated with intensive therapies with recognized substantial adverse event rates. In all these studies, the mortality rate for patients transfused with amotosalen-treated platelets has been comparable to that of conventional platelet components.[61,62,75,76] After the introduction of amotosalen-treated platelets into routine clinical practice in Europe, a hemovigilance reporting system was initiated to examine the incidence of acute reactions in the 24-hour post-transfusion period for 5000 transfusions of amotosalen-treated platelets. Preliminary analysis of 2512 transfusions has confirmed a low rate of acute transfusion reactions and tolerability of the treated platelets.[78]

Clinical Experience with Platelets Treated with Riboflavin and UV Light

A phase 1 clinical trial in healthy subjects has been conducted to assess the viability of autologous platelets treated with riboflavin (50 μmol/L) and ultraviolet light (5.0 J/cm^2, 265–370 nm) and stored in autologous plasma for 5 days.[79] The pH and metabolic parameters of the treated platelets were well maintained during storage. The average post-transfusion recovery (%) of the treated platelets was statistically lower than that of untreated autologous platelets (50.0 ± 18.9 vs 66.5 ± 13.4, $P < 0.05$) and the average survival (hours) was statistically reduced (104 ± 26 vs 142 ± 26, $P < 0.05$). While the viability of riboflavin-treated platelets was different from that of untreated platelets, in vitro studies of hemostasis suggested that functionality was adequately retained.[58] Further studies in thrombocytopenic patients are required to demonstrate that therapeutic efficacy has been retained and that the treated platelets are well tolerated after repeated transfusions.

POTENTIAL SYSTEMS FOR INACTIVATION OF PATHOGENS IN RED CELL CONCENTRATES

A number of laboratories have investigated the application of pathogen inactivation to red cell concentrates (Table 27–4). Red cells present a difficult environment

for pathogen inactivation owing to the light absorbance by hemoglobin and the viscosity of packed red cells. To date, most research efforts have explored the use of photodynamic methods, although photodynamic-associated damage may increase during prolonged red cell storage. Additional significant defects of the photodynamic systems include incomplete inactivation of pathogens, damage to red cells resulting in hemolysis and potassium leakage, increased binding of immunoglobulins, long treatment times, and the necessity to work at a reduced hematocrit or in thin-layer configurations to facilitate light activation. Recent work suggests that cellular damage due to active oxygen species can be ameliorated by the inclusion of scavengers or quenchers of active oxygen species,[80,81] but this modification further complicates the treatment process. More recently, several groups have developed nucleic acid–targeted processes that do not require light activation. The latter approach offers the potential to minimize nonspecific damage by active oxygen species to red cells and plasma proteins.

The initial red cell studies were conducted with porphyrin-based compounds and dyes such as merocyanine 540, methylene blue, and phthalocyanine (see Table 27–4). Each method had limited viral inactivation capacity and induced various levels of red cell injury. Subsequently, Wagner and colleagues described the use of a new phenothiazine compound, 1,9-dimethylmethylene blue (DMMB), which exhibited an improved inactivation spectrum compared with methylene blue and demonstrated less hemolysis and less immunoglobulin binding during storage after treatment.[82] The photodynamic damage due to 1,9-DMMB was diminished by the use of dipyridamole.[83] More recently, another photodynamic process which uses a thiopyrylium dye and dipyridamole to control oxidative membrane damage has been described.[84] None of these methods have reached the clinical trial stage.

Two groups have explored using nucleic acid targeted compounds that do not require photo-activation for nucleic acid inactivation. INACTINE (PEN 110), a nucleic acid–targeted compound, was reported to inactivate viruses, bacteria, and leukocytes in red cell suspensions.[85–87] The INACTINEs are stable monoalkylators that are immediately active upon addition to blood or red cell concentrates (Fig. 27–6). Red cells treated with PEN 110 were stored for 28 days, radiolabeled, and then transfused into chimpanzees. PEN 110 demonstrated no effect on the viability of chimpanzee red cells.[88]

PEN 110 was studied in a phase 1 trial of 12 healthy subjects to examine the effect of treatment on post-transfusion red cell recovery and life span. This trial was designed as a crossover study and utilized autologous red cells stored for 28 days before transfusion. In vitro studies were conducted with treated and control red cells stored for 42 days. In this study the PEN 110–treated red cells were exposed to sodium thiosulfate as a quenching reagent and washed before transfusion. Post-transfusion dual radiolabel recovery (%) was comparable to that of untreated cells (85.0 ± 5.0 vs 85.9 ± 2.7%), as was the half-life (days) (31.9 ± 8.2 vs 32.9 ± 3.3).[89] Over 42 days of storage, PEN 110–treated red cells demonstrated reduced metabolic activity, but cell-free hemoglobin levels and extracellular potassium levels remained within acceptable limits.

A phase 2 study was performed to evaluate the viability of PEN 110–treated red cells after 35 or 42 days of storage.[90] Healthy subjects (12 per treatment and storage cohort) were randomized to receive either treated or untreated autologous red cells stored for the assigned storage period. In this study, thiosulfate quenching was not used and the treated red cells were washed extensively prior to storage to remove residual PEN 110. These studies demonstrated comparable post-transfusion recoveries (%) after 42 days of storage as measured by a single radiolabel method (82.9 ± 5.7 vs 86.3 ± 8.7), but half-life of the PEN 110–treated red cells was reduced by approximately 30%. In vitro studies demonstrated a trend for decreased 2,3-DPG and ATP levels of treated cells compared with control cells. Subsequently, PEN 110–treated red cells were used in a phase 3 clinical trial for patients requiring transfusion support of acute and chronic anemia. These studies were halted when patients developed antibodies to the treated red cells. However, these studies have not been further described, and development of this technology was suspended.

Table 27–4 **Methods Used to Inactivate Pathogens in Red Cell Concentrates**

Reactive Agent	Target	Reference
Dihematoporphyrin	HIV, HSV, CMV, SIV, *Trypsnosoma cruzi*	146
Benzoporphyrin A	VSV, FeLV	147
Merocyanine 540	Friend LV	148
Merocyanine 540	HSV-1	149
Merocyanine 540	*Plasmodium falciparum*	150
Methylene blue	VSV	151
Methylene blue	VSV, Φ6, Sindbis, M13	152
Phthalocyanines	VSV	153
Phthalocyanines	VSV, Sindbis	145
PSR-Br	Φ6	154
Hypericin	HIV	155
1,9-DMMB	VSV, PRV, BVDV, Φ6, R17, EMC	82
Thiopyrylium	VSV, PRV, BVDV, HIV, DHBV	84
INACTINE	Porcine parvovirus, BVDV, HIV-1, VSV	156
S-303	HIV, DHBV, BVDV, bacteria	91

HIV, human immunodeficiency virus; HSV, herpes simplex virus; CMV, cytomegalovirus; SIV, simian immunodeficiency virus; VSV, vesicular stomatitis virus; FeLV, feline leukemia virus; Friend LV, Friend erythroleukemia virus; Φ6, bacteriophage; Sindbis, Sindbis virus; PSR-Br, brominated psoralen; PRV, pseudorabies virus; BVDV, bovine viral diarrhea virus; EMC, encephalo-myocarditis virus; R17, bacteriophage; DMMB, dimethylmethylene blue.

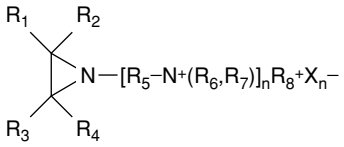

Figure 27–6 Structure of INACTINE compounds. PEN 110 is a member of the class.

Cook and colleagues developed a class of compounds known as anchor linker effectors (ALE) and frangible anchor linker effectors (FRALE) for inactivation of pathogens in red cell concentrates.[91] The FRALE compounds are composed of three moieties (Fig. 27–7): a nucleic acid–targeted intercalator group, an effector group for covalent addition to nucleic acid, and a central frangible bond facilitating compound degradation. The FRALES are stable at low pH and are activated by a pH shift upon addition to packed red cells suspended in residual plasma and a red cell additive solution at neutral pH. The FRALE compounds rapidly degrade to a negatively charged, inactive species after reaction, thus preventing further binding to DNA and RNA (Fig. 27–8). The lead compound, S-303 (100 µg/mL), upon addition to packed red cells (60% hematocrit), inactivated high titers of cell-free and cell-associated HIV, DHBV, VSV, HSV, BVDV, and both gram-negative and gram-positive bacteria.[92] Using a murine transfusion model, S-303–treated red cells exhibited post-transfusion recovery and life span comparable to those of untreated red cells.[91] In a second series of studies, dog red cells treated with S-303 exhibited post-transfusion recovery and life span comparable to those of untreated red cells.[92] Dogs transfused multiple times with allogeneic S-303–treated red cells failed to develop antibodies to S-303–treated autologous red cells, but some dogs did develop alloantibodies to untreated donor cells indicating an intact alloimmune response not directed against S-303–treated red cells. Other dogs transfused with S-303–treated red cells (10 mL/kg) 12 times over a 1-month period had no clinical or histopathologic evidence of toxicity. In addition, replacement of 80% of the blood volume of dogs with S-303–treated red cells using treatment concentrations up to 500 µg/mL resulted in no toxicity. S-303–treated red cells and S-300, the breakdown product of S-303, were not carcinogenic in a repeated transfusion study of transgenic heterozygous p53 knockout mice.[93]

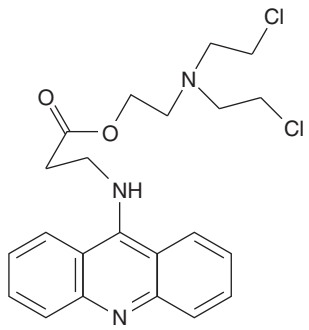

Figure 27–7 Structure of the frangible anchor linker effector (FRALE) compound S-303. The molecule consist of three parts: an anchor for nucleic acid intercalation, an effector region for covalent addition to nucleic acid, and a labile, "frangible" linker to facilitate S-303 degradation.

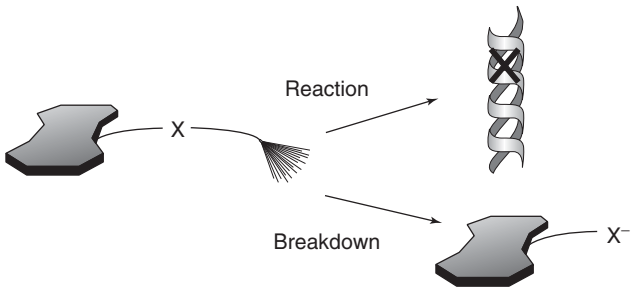

Figure 27–8 Mechanism of action for FRALE compounds. After addition to red blood cells, S-303 rapidly attaches to nucleic acid and then degrades to S-300, a negatively charged compound that does not bind to nucleic acid.

A prototype S-303 system was designed to inactivate infectious pathogens in plastic containers (Fig. 27–9). Using a closed system with a series of connected containers, S-303 (200 µmol/L) and glutathione (2 mmol/L) were incubated with red blood cell concentrates (200–250 mL). The red cells were incubated at room temperature for 8 hours, during which time pathogen inactivation was completed and S-303 degraded to the inert compound S-300. After incubation, the treated red cells were transferred to a plastic storage container with an integral CAD for storage for 35 to 42 days at 4°C. Evaluation of in vitro red cell properties after 42 days of storage demonstrated no differences in the following parameters: red cell ATP levels, extracellular potassium, hemolysis, and glucose consumption.[91] S-303–treated red cells advanced through preclinical safety studies and entered the clinical phase in 1998.

Three clinical trials with S-303–treated red cells have been completed in healthy subjects. The first was a controlled, two-arm, randomized trial in which the post-transfusion viability of S-303–treated, autologous red cells stored for 35 days after treatment was compared to that of untreated red cells stored for 35 days.[94] The study was designed to detect small differences in post-transfusion recovery. Twenty-one subjects were enrolled into the S-303 treatment group and 22 into the control group. The average post-transfusion recovery of

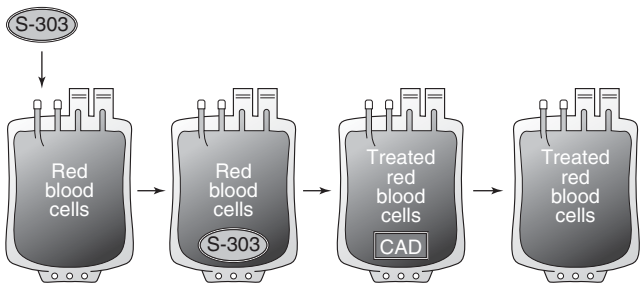

Figure 27–9 The prototype FRALE S-303 process for treatment of red blood cell concentrates. The treatment is conducted in a closed system. S-303 is maintained at low pH and is activated by addition to red cell concentrates at neutral pH. The inactivation process is conducted in full-sized units ranging in hematocrit from 60% to 80%. After addition of S-303 to the red cells, the plastic container is incubated at room temperature for 6 to 8 hours to complete pathogen inactivation. Following pathogen inactivation, the red cells are transferred to a plastic container with a compound absorption device (CAD) to reduce the levels of S-300. The red cells remain in contact with the CAD for up to 35 days of storage at 4°C.

35-day-old S-303 red cells was statistically lower than that of control red cells (78.7 ± 5.7% vs 83.9 ± 6.1%, $P = 0.002$), but recovery for both types exceeded 75%, the generally accepted threshold for viability of stored red cells. No adverse events were observed following transfusion of S-303 red cells.

A second phase 1 study was conducted in which the viability and potential immune response of healthy subjects to multiple exposures to autologous S-303–treated red cells were evaluated.[95] Subjects from the first study, of either treatment group, were invited to participate. The second study was initiated approximately 6 months after completion of the first study; thus, there was an interval of 6 to 9 months before the next transfusion exposure. In the second study, each subject donated a unit of blood that was processed into packed red cells. All the units were treated with S-303 and stored for 35 days. At four times, approximately 7 days apart, during the 35-day storage period, subjects were transfused with an aliquot of autologous S-303–treated red cells. The final aliquot on day 35 was radiolabeled with 51-Cr to measure post-transfusion viability. The red cell recovery 24 hours after transfusion of S-303–treated red cells was compared with each subject's red cell recovery in the first study. Sixteen subjects received control red cells in the first study and S-303 red cells in the second study. The average red cell recovery in the first study with control cells was 82.6 ± 6.4%, which was not statistically different from the average recovery of 84.3 ± 6.4% after transfusion of S-303 cells in the second study ($P = 0.30$). Twelve subjects received S-303 red cells in the first study, with an average recovery of 77.5 ± 6.6%, and after transfusion in the second study, these subjects demonstrated an average recovery of 79.2 ± 6.6%. After exposure to either four or five aliquots of S-303–treated red cells, no subjects developed antibodies directed against S-303 red cells.[95]

A third phase 1 study was conducted in 29 healthy subjects using a randomized crossover design to measure both post-transfusion recovery and life span of autologous S-303–treated red cells compared with control red cells processed with conventional methods.[96] Both types of red cells were stored for 35 days. The study was designed to detect small differences in red cell viability. A small difference in 24-hour post-transfusion recovery of S-303–treated red cells was detected compared with conventional red cells (81.7 ± 6.3% vs 84.5 ± 6.2%, $P = 0.048$). However, mean half-life was identical (37.4 ± 8.9 vs 37.4 ± 6.7 days, $P = 1.0$).

On the basis of the three phase 1 red cell clinical trials, phase 3 clinical trials were initiated to evaluate the therapeutic efficacy and safety of S-303–treated red cells in patients for the two major indications for red cell transfusion: acute and chronic anemia. For the indication of acute anemia, a randomized, two-arm controlled study to evaluate the response to transfusion in 200 patients undergoing cardiovascular surgical procedures was initiated.[97] The primary end point of this study was the composite incidence of renal failure, myocardial infarction, and death as a reflection of tissue oxygenation efficacy during correction of acute anemia. For the therapeutic indication of chronic anemia, a randomized, two-period crossover study enrolling patients with thalassemia and sickle cell anemia requiring chronic transfusion support was initiated. The primary end point of this study was the consumption of hemoglobin (g/kg body weight per day) over approximately 6 months.[98] Both studies were under way when two patients in the chronic trial developed positive crossmatch reactivity to S-303–treated red cells.[99] The sponsor elected to suspend both studies until the mechanism of the immunologic response could be elucidated.

Evaluation of sera from two patients with consistently reactive crossmatches to S-303–treated red cells confirmed that the reactivity was directed against the acridine (anchor moiety) portion of S-303.[99] The antibody was low titer and did not promote red cell phagocytosis in a monocyte-macrophage ingestion assay.[100] No patients in the acute anemia trial developed crossmatch reactivity with S-303–treated red cells. Prior to detection of positive crossmatch reactivity in the two chronic study patients, 148 patients completed the acute anemia study. Analysis of results from the study demonstrated that the primary end point was met, as well as all secondary end points.[97] The treated red cells were well tolerated and the safety profile was comparable to that of conventional red cells. In the chronic trial, no patients completed the study, but an interim analysis of data suggested that S-303–treated red cells were similar to conventional red cells for transfusion support of chronic anemia.[98] Further investigation of the S-303 process resulted in development of a modified process using an increased concentration of glutathione. Additional clinical trials are required to demonstrate that this modified process avoids cross-reactivity and alloimmunization in chronically transfused patients.

SYSTEMS FOR INACTIVATION OF PATHOGENS IN PREPARATION OF FRESH FROZEN PLASMA

The solvent detergent (SD) process for inactivation of enveloped viruses in plasma used for transfusion was introduced into clinical practice.[101] The SD process is generally highly effective against enveloped viruses, although very recently new evidence has been reported to suggest that some enveloped viruses, such as vaccinia, may be resistant to SD treatment.[102] Moreover, since SD treatment is not effective against nonenveloped viruses, concern has been expressed over the potential for transmission of these pathogens as a result of pooling with failure to inactivate resistant viruses.[103] Despite these issues, solvent detergent fresh frozen plasma (SD-FFP) has demonstrated therapeutic efficacy for replacement of congenital[104] and acquired coagulation factor deficiencies.[105,106] Furthermore, since SD-FFP does not contain high-molecular-weight multimers of von Willebrand factor (vWF), it has been advocated for use during therapeutic plasma exchange (TPE) therapy of thrombotic thrombocytopenic purpura (TTP).[104] Transfusion of SD-FFP has been well tolerated with a low incidence of transfusion reactions and adverse events.[107]

With increasing experience, other studies with SD-FFP documented mild to marked decreased levels of antithrombotic proteins: protein S and plasmin inhibitor.[108] Mast and co-workers confirmed that SD-FFP has markedly reduced levels of the antithrombotic proteins antiplasmin and antitrypsin and that these reduced levels are due to conformational changes induced by detergent treatment.[109] The clinical significance of these observations was unclear when initially reported, but subsequent reports indicated that there was an increased incidence of thrombotic events after large volume exposure during liver transplantation[110] and TPE for TTP.[111,112]

The SD process utilizes pooled plasma from 100 to 2500 donors and is not amenable to a single-unit viral inactivation process. In Europe, a single-unit treatment process using the

phenothiazine dye methylene blue (MB) and long wavelength visible light has been used in clinical practice for preparation of fresh frozen plasma (MB-FFP).[113] MB exhibits limited binding affinity for nucleic acid; rather, the predominant mechanism of action is photodynamic via production of active oxygen species. More importantly, methylene blue is not effective against intracellular viruses owing to conversion to the inactive leuko–methylene blue species. Certain coagulation proteins, primarily factor VIII and fibrinogen, are sensitive to MB treatment and undergo a decrease in functional activity during treatment ranging from 30% to 40% of the levels in untreated plasma.[113] More recent studies with a commercial system using both fresh and frozen plasma with leukocyte reduction and a device to reduce the residual levels of MB demonstrated decreases in factor VIII activity ranging from 24% to 29%.[114] MB-FFP did provide adequate levels of fibrinogen, factor VIII, factor XIII, and vWF in cryoprecipitate, and the corresponding cryosupernatant fraction was depleted of the high-molecular-weight vWF multimers.[115]

MB-FFP has been well tolerated when transfused into healthy subjects.[116] Reports of randomized, controlled clinical trials for MB-FFP for the major therapeutic indications of FFP use are limited, despite transfusion of more than 1 million units in Europe.[117] A single study compared the usage of SD and MB-FFP in cardiac surgery patients and reported improved levels of protein S and α_2-antiplasmin with MB-FFP.[118] Several reports have indicated that MB-FFP use for TPE to treat TTP resulted in reduced efficacy.[119,120] A more generalized experience with MB-FFP was reported based on a retrospective analysis of three 1-year periods before and after adoption of MB-FFP.[121] This study indicated that use of MB-FFP resulted in increased use of FFP and cryoprecipitate owing to reduced hemostatic efficacy of the treated plasma. These observations have yet to be confirmed by additional studies.

A photochemical method using amotosalen and UVA light has been developed to inactivate viruses in single units of plasma prepared as FFP. Using a prototype configuration, with 3 J/cm^2 of UVA delivered in approximately 3 minutes, the average log reduction of virus was cell associated–HIV 6.4 ± 0.2, cell-free HIV >5.9 (95% CI), DHBV 5.4 ± 0.4, and BVDV 6.7 ± 0.4 after only 0.5 J/cm.^{2} Because the amotosalen process is nucleic acid–targeted, it has demonstrated some inactivation efficacy of several nonenveloped viruses (e.g., rotavirus, calicivirus, and blue tongue virus). After PCT, FFP units were treated for 1 hour with a CAD to reduce residual amotosalen concentration followed by freezing (−20 °C). Coagulation activity of thawed amotosalen FFP units was compared with matched-control FFP units without PCT or CAD. Retained factor activities (% of control ± SD) were clottable fibrinogen, 87 ± 3%; factor V, 98 ± 2%; factor VII, 86 ± 2%; factor VIII, 73 ± 4%; factor IX, 95 ± 4%; factor X, 98 ± 4%; and factor XI, 91 ± 5%.[122] This system has been modified to treat up to 650 mL of plasma in a single process using a flow instead of a batch CAD to shorten processing time.[123] This system is compatible with either apheresis plasma collections[124] or pools of 2 or 3 units of whole blood–derived plasma.

Plasma prepared with the prototype system has been evaluated in a series of clinical trials. A single blinded, crossover, stepwise ascending dose clinical trial (100–1000 mL) was conducted in 15 healthy subjects. No adverse events were attributed to transfusion of amotosalen FFP at any dose and no clinically significant changes in post-transfusion coagulation, chemistry, or hematology profiles.[125,126] Peak post-transfusion levels (9 ± 1 ng/mL) of amotosalen were determined immediately after transfusion of 1000 mL of treated plasma and 18 to 24 hours later (0.52 ± 0.1 ng/mL).

In a second study, using a randomized crossover design, Hambleton and colleagues compared the pharmacokinetics of factor VII and the post-transfusion recoveries of factors II, VII, IX, and X in 27 healthy subjects after transfusion of conventional and treated FFP. Subjects received a 4-day regimen (7.5 mg/day) of warfarin prior to each study transfusion to suppress endogenous factor VII levels.[127] At the start of the study, subjects donated 2 L of FFP by apheresis collection. One liter of plasma was treated with amotosalen and frozen at −18 °C; the other liter was prepared as standard FFP and stored at −18 °C. Each subject received both types of FFP in random order. Prior to each transfusion, subjects were given 4 days of warfarin therapy followed by transfusion of 1 L of amotosalen FFP or untreated FFP. Warfarin therapy resulted in reduction of factor VII levels to approximately 30% of normal. No statistical differences (Wilcoxon signed-rank test) of clearance, recovery, half-life, or mean residence time (MRT) for factor VII were observed between amotosalen and control FFP.[127] No differences in recoveries of other factors (II, IX, and X) were observed. Transfusion of amotosalen FFP provided acceptable coagulation factor preservation without adverse effects. The anticoagulant challenge crossover trial demonstrated that transfusion of amotosalen FFP yielded therapeutic coagulation factor increments similar to those of standard FFP.

A phase 2 randomized, controlled, pilot study of amotosalen FFP was completed in 13 patients with acquired coagulopathy to evaluate the response of prolonged prothrombin (PT) and partial thromboplastin times (PTT) to transfusion with amotosalen FFP. Patients with a diagnosis of acquired coagulopathy undergoing minor invasive procedures were randomized to transfusion with either amotosalen FFP or conventional FFP.[128] The average PT and PTT were prolonged before FFP transfusion and responded similarly to transfusion with either amotosalen or conventional FFP. The response lasted 8 to 12 hours, and amotosalen FFP demonstrated acceptable control of bleeding in patients undergoing invasive procedures, such as liver biopsy. Peak post-transfusion plasma levels of amotosalen were 3.10 ± 1.65 ng/mL.

A phase 3 clinical trial program for amotosalen FFP was conducted to assess therapeutic efficacy and safety for the major indications for FFP transfusion: congenital coagulopathy, acquired coagulopathy, and therapeutic plasma exchange. The first study evaluated the post-transfusion recovery and clearance of specific coagulation factors in 34 patients with congenital coagulopathies requiring FFP transfusion.[129] This open-label, single arm study enrolled patients with deficiencies of factors I, II, V, VII, X, XI, and protein C. Enrolled patients received at least one transfusion of amotosalen FFP (suggested dose of 15 mL/kg) to measure the recovery and clearance of the specified deficient clotting factor. Patients were eligible to receive additional amotosalen FFP transfusions as required to manage active bleeding or for prophylaxis during surgical procedures. This study demonstrated that the post-transfusion clearance of factors V, VII, X, XI, and protein C was comparable to reported values.[129] The clearance of factors I, II, and XIII were shorter than the reported values but provided acceptable post- transfusion recoveries for support of patients.[129] Pretransfusion

prolonged prothrombin times (PT) and PTT corrected after transfusion of amotosalen FFP.[129] Seventy-seven transfusions were administered for management of active bleeding or for prophylaxis against bleeding during surgical procedures. In each case, acceptable hemostasis was achieved after transfusion.[129] Some patients received repeated transfusions of amotosalen FFP over 2 years. Peak plasma levels of amotosalen immediately after transfusion were 8.42 ± 2.72 ng/mL, similar to those observed in healthy subjects. The treated plasma was well tolerated, and the adverse event profile was similar to that reported for conventional plasma.

A controlled, double-blinded, randomized study of 121 patients with acquired coagulopathy, largely due to chronic liver disease, was conducted to evaluate therapeutic efficacy and safety for this indication.[130] Prior to elective surgical procedures, including liver transplantation, patients were randomized to receive either conventional FFP or amotosalen FFP for up to 7 days of support. The primary end point of this study was the response of PT and PTT to FFP transfusion. This study demonstrated correction of the PT and PTT responses on a dose- and patient weight–adjusted basis, hemostasis, and use of blood products comparable to that of patients supported with conventional FFP. The mean incremental recovery for factor VII was not different between the treatment groups (0.69 ± 1.80 vs 0.48 ± 0.76 IU/dL/IU/kg). After large doses of amotosalen FFP, peak post-transfusion plasma levels of amotosalen (5.4 ± 3.5 ng/mL) were lower than those of nonbleeding healthy subjects. Transfusion of amotosalen FFP was well tolerated in this patient group.

A double-blinded randomized study of patients with TTP was subsequently carried out.[131] In this study, 35 patients were assigned to receive up to 30 days of TPE with either conventional FFP or amotosalen FFP. The primary end point was the proportion of patients in remission in each treatment group after 30 days of TPE. Patients who failed to reach remission after 30 days of TPE were eligible to continue TPE for an additional 30 days. The rates of remission were not different between the treatment groups (82 vs 89%, $P = 0.66$). In addition, time to remission, relapse rates, and time to relapse were not different for patients treated with amotosalen FFP. Despite the exposure to large volumes of amotosalen FFP, peak plasma levels were within the same range as the other patient groups (5.4 ± 3.6 ng/mL). As in the other studies, amotosalen FFP was well tolerated and the safety profile was similar to that for patients supported with conventional FFP.

CONCLUSIONS

New threats to the safety and availability of labile blood components continue to evolve. To meet these challenges, new tests and increased donor restrictions have been implemented, but transfusion-transmitted infections persist. Robust pathogen inactivation systems for treatment of each blood component have been developed and are in various stages of clinical trials in the United States and Europe. However, progress has been slow, and problems have been encountered during development. Despite these hurdles, systems for treatment of platelets and plasma are in clinical use, and as experience is gained these technologies may result in a paradigm shift for prevention of transfusion-transmitted infections. The availability of pathogen inactivation systems for all blood components, ultimately, may permit modification of current testing strategies to take advantage of a stratified, integrated approach to transfusion safety by using pathogen inactivation and a modified testing strategy to achieve higher levels of blood component transfusion safety. As new pathogens of clinical importance are identified in the donor population, both pathogen inactivation and testing strategies will require further modification to meet new challenges.

Chapter 28

Irradiated Products

Naomi L. C. Luban • Edward C. C. Wong

INTRODUCTION

Transfusion-associated graft-versus-host disease (TA-GVHD), an often fatal alloimmune complication mediated by donor T cells in the blood component, was first reported in the 1960s in individuals with hematologic malignancies and in infants with congenital immunodeficiencies who developed "runting disease" after blood transfusion.[1]

Since these early reports, the spectrum of individuals at risk has expanded, the pathogenesis has been partially elucidated, and preventive strategies have been established.[2–4] Despite these advances, many unanswered questions remain. For example, there are no adequate estimates of prevalence. In Japan, an estimated annual incidence of one TA-GVHD case per 212 transfusions has been calculated based on homozygosity for one-way human leukocyte antigen (HLA) haplotype sharing, the use of familial donors, and the use of fresh rather than stored red blood cells (RBCs).[5] In the United Kingdom and Canada, in contrast, risk estimates are much lower as determined by adverse transfusion outcome reporting. The *S*erious *H*azards *o*f *T*ransfusion (SHOT) study in the United Kingdom has identified only 13 cases from 1996 to present, although all were fatal.[6] In Canada, mathematical modeling by Kleinman and colleagues estimated the magnitude of risk to be between 1:12,893 and 1:21,157, but based on cases reported and other factors a true risk of less than 1 per million units transfused is cited.[7] No incidence figures are available for the United States, and it is likely that under-recognition and under-reporting are common. Additionally, while the pathogenesis of TA-GVHD partially resembles that of GVHD in the setting of hematopoietic stem cell transplantation, further, more detailed investigations of TA-GVHD have been hindered by the lack of well-established animal models. Instead, investigators typically utilize the classic parent-to-F1 hybrid mouse model of GVHD, which may or may not provide the correct tool for TA-GVHD investigations.[8]

Given the almost uniform lethality of TA-GVHD, extensive clinical investigations have fortunately led to the development of pretransfusion irradiation methods that uniformly prevent TA-GVHD. The technical and regulatory aspects of these methodologies are addressed in detail in this chapter. Since irradiation devices are not available in all transfusion settings, attention has recently focused on alternative approaches to prevention. Data are accumulating to suggest that filtration and nucleic acid–targeted pathogen reduction technologies may remove or inactivate donor leukocytes, respectively, to the extent that TA-GVHD is also prevented, although further study and validation are required.

PATHOGENESIS OF TA-GVHD

Three prerequisites for the development of GVHD in the transplant setting have been proposed: (1) differences in histocompatibility between recipient and donor, (2) presence of immunocompetent cells in the graft, and (3) inability of the host to reject the immunocompetent cells. A similar set of circumstances underlie TA-GVHD. First, in almost all cases, leukocytes in homologous blood components are mismatched with the transfusion recipient at HLA and minor histocompatibility loci. Second, transfused donor leukocytes are immunologically functional, except in circumstances in which they have been specifically inactivated (e.g., following gamma-irradiation). And third, the commonality between many of the patients at risk for TA-GVHD is their inability to reject transfused leukocytes, either due to immune immaturity (low-birth-weight neonates) or iatrogenic immunosuppression (transplant recipients). The development of TA-GVHD in additional clinical settings illustrates the importance of these factors. For example, most immunocompetent recipients destroy transfused donor T cells through lymphocytolysis and therefore do not develop TA-GVHD. However, transfusion from an HLA homozygous donor to an HLA heterozygous, but immunocompetent, recipient who shares one HLA haplotype may result in failure of recognition of the donor cells as foreign.[9,10] This so-called "one-way HLA match" is often responsible for the development of TA-GVHD in immunocompetent recipients, such as might occur in familial (directed) blood transfusions, in populations with limited HLA diversity, and when HLA-matched platelet transfusions are administered. In these cases, the non-self HLA or minor histocompatibility antigens of the host, or both, stimulate clonal expansion of donor T cells and the induction of an inflammatory response that is ultimately responsible for clinical manifestations of TA-GVHD.

Studies of the pathogenesis of TA-GVHD, both in vitro experiments as well as animal investigations, have begun to define roles for donor leukocyte subsets in the process. Among leukocytes, donor T cells play the most prominent role in disease pathogenesis. CD4+ T cells (sometimes known as T-helper cells) can be functionally divided into Th1 and Th2 subsets. Th1 CD4 T cells secrete interleukin-2 (IL-2), while Th2 CD4 T cells produce IL-4, IL-5, IL-6, IL-10, IL-13, and lesser amounts of tumor necrosis factor–α (TNFα). Th1 and Th2 both produce IL-3 and granulocyte-macrophage colony-stimulating factor. The type 1 cell is proinflammatory and induces cell-mediated immunity, whereas the type 2 cell is considered anti-inflammatory. Differentiation toward Th1 or Th2 is a complicated process that involves early exposure

to IL-4 or IL-12, the type of antigen-presenting cells, costimulating molecules, and the presence of macrophages and their unique cytokines.

On the basis of their work in mice, Ferrera and colleagues proposed a three-step process for the development of acute GVHD in the transplant setting, including the involvement of T-cell subsets. In this model (Fig. 28–1), host tissue damaged through irradiation or chemotherapy secretes TNFα and IL-1, which enhance recognition of host histocompatibility antigens by donor T cells. Donor T-cell activation results in proliferation of Th1 T cells and secretion of IL-2 and TNFα, which in turn further activate T cells and induce cytotoxic T- lymphocyte (CTL) and natural killer (NK) responses.

Additional studies have shown that donor and residual host phagocytes are stimulated to produce IL-1, TNFα, and the free radical nitric oxide (NO), which has further deleterious effects on host tissues. In addition, NO up-regulates alloreactivity and mediates the cytotoxic function of macrophages.[11] A secondary triggering signal initiates a subsequent stage in the disease process wherein lipopolysaccharide (LPS) stimulates gut-associated macrophages and lymphocytes, stimulates keratocytes and dermal fibroblasts, and further promotes the inflammatory response and end-organ damage that are classic hallmarks of the disorder.

Whether the development of TA-GVHD is dependent on similar mechanisms remains an open question. To begin to address this question, the importance of CD4 and CD8 T cells in the pathogenesis of TA-GVHD has been studied by Fast and coworkers[12] in a mouse model and by Nishimura and associates[13] in a patient with TA-GVHD. Their findings are further supported by clinical correlation in patients with human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS).[14] In the mouse, depletion of CD4+ cells increases the number of donor cells needed to induce TA-GVHD, whereas depletion of CD8+ or NK cells, or both, decreases the number of donor cells needed to induce the disorder. In HIV and AIDS, there has been only one report of TA-GVHD[15] despite widespread use of supportive transfusion and profound immunosuppression. This observation is consistent with the concept that

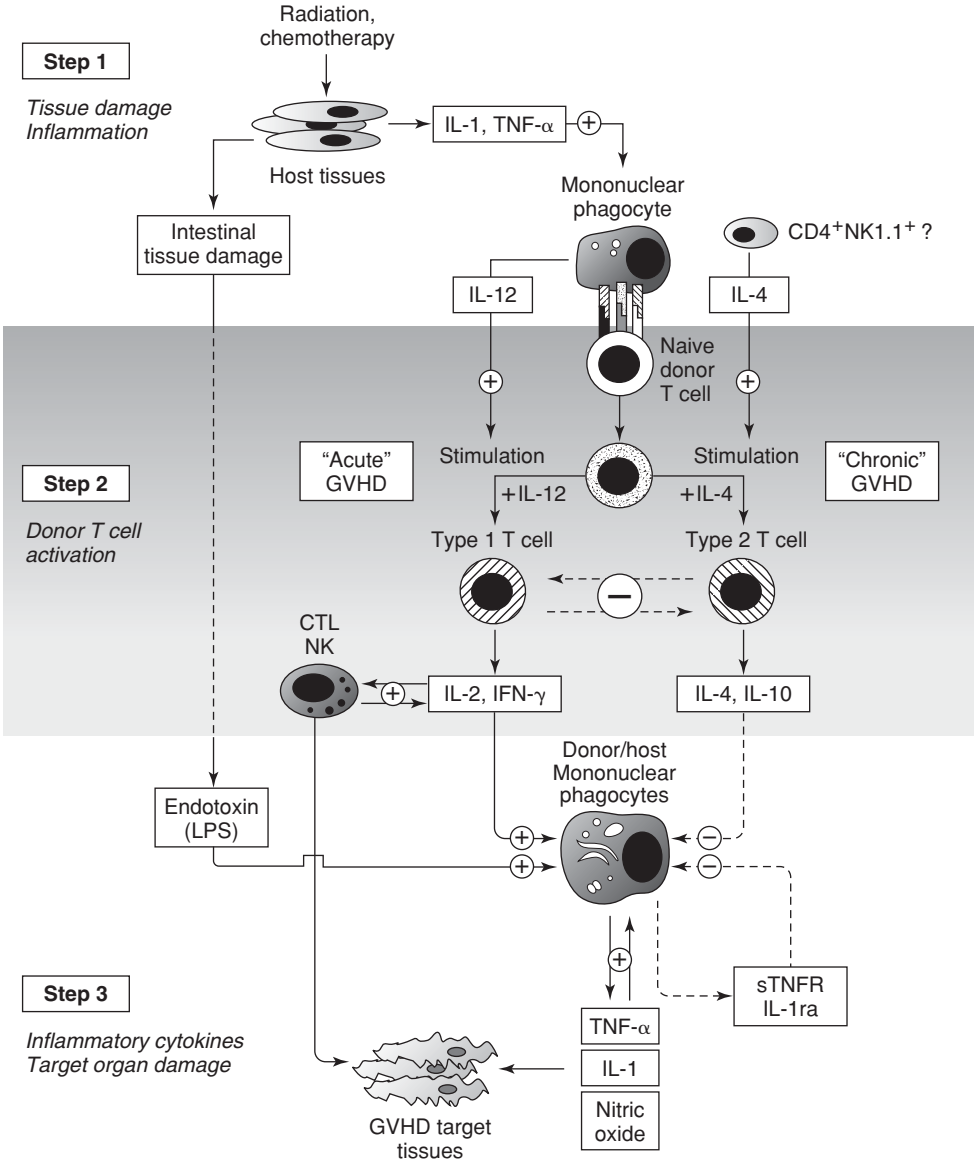

Figure 28–1 Proposed interactions between T-cell cytokines and mononuclear phagocyte–derived cytokines during graft-versus-host disease (GVHD). IFN, interferon; IL-1, interleukin-1; LPS, lipopolysaccharide; sTNFR, soluble tumor necrosis factor receptor; TNFα, tumor necrosis factor–α.

early depletion of CD4 may well protect against establishment of TA-GVHD. Additionally, expansion and activation of NK and CD8+ lymphocytes against HIV-infected CD4 T cells may limit the development of the GVHD process.

Since donor leukocytes must persist to cause TA-GVHD, other investigators have evaluated clearance of leukocytes after transfusion.[16] In 1996, Busch and colleagues[17] demonstrated a thousand-fold expansion of donor lymphocytes in the circulation of otherwise healthy recipients 3 to 5 days after transfusion for elective orthopedic procedures. Within 2 weeks, the allogeneic cells were cleared. In contrast, in a study of adult trauma victims who received large numbers (4 to 18 units) of fresh-packed RBCs, 8 of 10 had long-term persistence of donor leukocytes with confirmed microchimerism (MC). Two of the eight had persistence of MC when studied as long as 1.5 years after transfusion.[18] These studies have been further expanded in additional patients transfused for acute trauma who received nonleukoreduced[17] or leukoreduced[19] products. That MC in some cases persisted for years[18] recently has been confirmed and attributed to a single donor source from which leukocytes expanded over time.[18,20] These studies suggest that transfusion during a period of diminished lymphocyte responsiveness may result in a microchimeric state with persistence of functional donor leukocytes, possibly with long-term consequences.

Wang-Rodriquez and associates[21] studied post-transfusion immune modulation in 14 premature infants and identified two of six female infants, transfused with nonleukodepleted RBCs, who experienced transient MC detected by Y chromosome PCR amplification. In both, these cells were cleared by 2 weeks after transfusion. An additional three infants who received leukodepleted RBCs also had transient MC.

Vietor and coworkers[22] studied 9 surviving recipients of intrauterine transfusion whose donors were still available for testing. Using fluorescence in situ hybridization, PCR of Y chromosome–specific sequences, and assays for the frequencies of CTL and T-helper lymphocyte precursors, they detected true MC in 6 of 7 young adults studied 20 years after transfusion. Reed and colleagues[23] have developed sequence-specific amplification of DRB1, which permitted identification of minor chimeric populations at the 0.01% level. The establishment of stable MC and identification of its biological consequences are critical for pediatric patients who are expected to live to adulthood and may well be stable transfusion-induced chimeras, an intriguing and at the same time potentially worrisome occurrence. The persistence of MC may predispose to autoimmune disease,[24–26] chronic GVHD, and recurrent abortion[27] and may serve as an allogeneic stimulus of latent viral reactivation in the recipient.

In a mouse system, allogeneic male donor WBCs derived from C57BL/6 mice persisted in female BALB/c recipient mice and their survival was unaffected by irradiation. Although the experimental model could not differentiate nonproliferative from proliferative WBC, these data set the stage for additional studies on MC and post-transfusion WBC kinetics. Fast and colleagues studied the effects of different forms of irradiation on murine splenocytes to better understand inhibition of both in vitro and in vivo proliferative responses. Among their findings was that the genotype of the donor-recipient pair regulates recipient alloantibody formation, a conclusion suggested by studies of prolonged MC in humans.[19] They also showed that the accelerated elimination of donor cells from recipient lymphoid compartments might be due to altered expression of cell surface molecules like CD31, CD47, and CD200, a phenomenon yet to be confirmed in human studies.

CLINICAL MANIFESTATIONS OF TA-GVHD

Fever, anorexia, nausea, vomiting, and diarrhea typically develop 7 to 10 days post-transfusion. Skin manifestations of TA-GVHD are variably severe and begin as an erythematous maculopapular eruption that may proceed to erythroderma with bullae and frank desquamation. Gastrointestinal bleeding is commonly seen, usually as bloody diarrhea. Hepatic dysfunction with transaminitis and hyperbilirubinemia, including a progressively increasing direct fraction, is also seen. In contrast to acute GVHD in the setting of allogeneic transplantation, TA-GVHD leads to severe pancytopenia because donor T cells attack marrow hematopoietic cells. This often results in the death of the patient. The diagnosis typically is made at postmortem examination and is based on pathognomonic histopathologic findings of donor lymphocyte infiltration and expansion in skin, lymph nodes, liver, and the gastrointestinal tract.[28]

DIAGNOSIS OF TA-GVHD

Clinical suspicion may warrant a skin biopsy, which often reveals vacuolization of the epidermal basal cell layer, dermal-epithelial layer separation, and formation of bullae. Other findings include mononuclear cell migration into the epidermis, hyperkeratosis, and dyskeratosis. Liver biopsies may reveal eosinophilic infiltration and degeneration of small bile ducts, peripheral inflammation, and lymphocyte infiltration. The bone marrow findings are classically those of "empty marrow," with pancytopenia, fibrosis, and some lymphocytic infiltration.

Definitive confirmation of TA-GVHD is more complicated. Several methods have been utilized to identify lymphocytes of foreign origin in the patient's circulation or in affected tissues. Serologic HLA typing, DNA-based HLA class II typing, karyotype analysis, restriction fragment length polymorphism analysis using probes from both HLA and non-HLA regions, and genetic fingerprinting have all been used.[29–33] Fibroblast and buccal mucosal cells of the recipient are often needed, as the lymphocytolysis accompanying the disorder prohibits standardized serologic HLA typing using recipient lymphocytes. Alternatively, parental or familial specimens may be necessary to deduce a recipient's HLA type.[34] Donor lymphocytes in attached remaining segments from suspected blood products often require PCR amplification and sequence-specific oligonucleotide probe methodologies to provide confirmation of donor cell origin.[35]

GROUPS AT RISK FOR TA-GVHD

Patients in whom TA-GVHD may develop have been described in a number of reviews,[2–4,10,11,36,37] and this remains an area of active discussion. For example, on the basis of two reports of TA-GVHD in older infants with severe combined immunodeficiency,[18,35] it has been recommended that infants well past the neonatal age group be considered at risk.[38,39] Because of the lack of adequate animal models and laboratory tests to identify individual TA-GVHD risk, many reports stratify the

need for irradiation using such terms as *clearly indicated* or *probably indicated*.[3,36,37] In reality, the spectrum of individuals at risk is likely to grow as intensive immunomodulatory therapies expand beyond oncologic disease and transplantation (Table 28–1).

THERAPY FOR TA-GVHD

The rapid progression of clinical manifestations of the disorder and similarity of clinical presentation to that of viral, drug-related, or disease-related enteropathy and hepatocellular damage contribute to the high mortality rates. Anecdotal success has been reported with immunosuppressive treatment including cytoxan, antithymocyte globulin, and high-dose corticosteroids. Recently, the serum protease inhibitor nafamostat mesylate has been used with some success.[40,41] The effectiveness of hematopoietic stem cell transplantation is mixed.[35,42]

PREVENTION OF TA-GVHD

Irradiation

Among methodologies (e.g., irradiation, photoinactivation, pegylation, and ultraviolet [UV] light) that can be used to prevent TA-GVHD, only irradiation of whole blood and cellular components is currently accepted by the U.S. Food and Drug Administration (FDA). Exposure of cellular components to ionizing radiation results in the inactivation of T cells by damage to nuclear DNA either directly or through generation of ions and free radicals that have damaging biological actions. Irradiation prevents post-transfusion donor T-cell proliferation in response to host antigen-presenting cells, which, in turn, abrogates GVHD.[43–46] Two types of ionizing radiation—gamma rays and x-rays—are equivalent in inactivating T cells in blood components at a given absorbed dose. Gamma rays originate from the radioactive decay process within the atomic nucleus of cesium 137 (^{137}Cs) or cobalt 60 (^{60}Co). Freestanding blood bank gamma-irradiators, which are the predominant instruments for blood component irradiation, use either of these two isotopes as the irradiation source.

In contrast, x-rays are generated from the interaction of a beam of electrons with a metallic surface. Linear accelerators typically used to generate x-rays for clinical radiation therapy (teletherapy) may serve as an irradiation source for blood and blood components. The FDA has also approved the use of a freestanding x-ray machine (RadSource RS3000, Coral Springs, Fla.) for irradiation of blood components.

Instrumentation for Irradiation

The basic operating principles and configurations of a freestanding irradiator with either a ^{137}Cs source or a linear accelerator are shown schematically in Figure 28–2. With a freestanding ^{137}Cs irradiator, blood components are contained within a metal canister that is positioned on a rotating turntable. Continuous rotation allows the gamma rays, originating from one to four closely positioned pencil sources, to penetrate all portions of the blood component. The number of sources and their placement depend on the instrument and model. The speed of rotation of the turntable is also specific to each model. A lead shield encloses the radiation chamber, protecting the operator from radiation exposure. Freestanding irradiators employing ^{60}Co as the source of gamma rays are comparable except that the canister containing the blood component does not rotate during the irradiation process; rather, tubes of ^{60}Co are placed in a circular array around the entire canister within the lead chamber. When freestanding irradiators are used, the gamma rays are attenuated as they pass through air and blood but at different rates.[45] The magnitude of attenuation is greater with ^{137}Cs than with ^{60}Co sources.

Linear accelerators generate a beam of x-rays over a field of given dimensions. Routinely, the field is projected on a tabletop structure. The blood component is placed (flat) between two sheets of biocompatible plastic several centimeters thick. The plastic on the top of the blood component (i.e., nearer to the radiation source) generates electronic equilibrium of the secondary electrons at the point where they pass through the component container. The plastic sheet on the bottom of the blood component provides radiation backscattering that helps ensure homogeneous delivery of the x-rays. The blood component is usually left stationary during delivery of the entire x-ray dose. Alternatively, it may be inverted when half of the dose has been delivered, although additional data on this practice are needed. Guidance is available on the FDA website (http://www.fda.gov/cder/guidelines.htm).[47] In June 1999, the FDA licensed the first x-ray irradiator based on principles utilized in standard x-ray machines. This irradiator does not require federal or nuclear regulatory licensing or reporting, a shielded room for operation, or special floor reinforcement.

Table 28–1 Clinical Indications for Irradiated Products

In Fetus/Infant
Intrauterine transfusion
Prematurity
Congenital immunodeficiency
Exchange transfusion for erythroblastosis
In Child/Adult
Congenital immunodeficiency
Hematologic malignancy or solid tumor (neuroblastoma, sarcoma, Hodgkin's disease where ablative chemotherapy and/or radiotherapy is administered)
Peripheral blood stem cell or marrow transplant
Recipient of familial blood donation
Human leukocyte antigen–matched products
Lupus or any other condition requiring fludarabine
Potential Indications
Recipient and donor pair from a genetically homogeneous population
Other patients with hematologic malignancy or solid tumor receiving immunosuppressive agents
Infant/child with congenital heart disease with 22 qll deletions, other than DiGeorge syndrome
Recipient and donor pair from genetically less homogeneous populations
Those receiving "less intensive" immunosuppressive regimens
No/Limited Indications
Patients infected with HIV
Term infants
Obstetric, surgical, and general medicine patients

Components to Be Irradiated

The content of viable T lymphocytes is the single most important factor in determining whether a blood component can induce TA-GVHD. On the basis of animal models and estimates from the clinical bone marrow transplant literature, 5×10^4 to 1×10^5 T cells per kilogram produces GVHD in ablated hosts[46]; a greater number is probably needed in a nonablated recipient. The content of T lymphocytes in each blood component differs depending on the donor's initial lymphocyte count, the method of collection, and any postcollection manipulation and processing. There are probably sufficient lymphocytes in almost all blood products to induce TA-GVHD in a susceptible recipient (Table 28–2). As storage time increases, fewer viable lymphocytes can be isolated from RBC and platelet concentrates. However, a detailed analysis of lymphocyte subsets in different blood products has not been produced, making assessment of the TA-GVHD risk for a specific class of product and a subcategory of patients difficult. Further, there could be a cumulative or synergistic effect of viable T cells present in the multiple transfusions received by a given patient whose own immunologic status fluctuates with time from treatment and infectious disease state.

For patients at risk for GVHD, all components that might contain viable T cells should be irradiated. These include units of whole blood and cellular components (RBCs, platelets, granulocytes), whether prepared from whole blood or by apheresis (Table 28–3). All types of RBCs should be irradiated, whether they are suspended in citrated plasma or in an additive solution. Data support retention of the quality of irradiated RBCs after subsequent freezing and thawing.[48,49] If frozen/thawed RBC units are intended for GVHD-susceptible individuals and have not been previously irradiated, they should be irradiated because it is known that such components contain viable T cells.[50] Filtered RBC products should also be irradiated. Extensive leukoreduction

Table 28–2 **White Blood Cell (WBC) Content of Different Blood Components**

Component	Volume (approximate)* (mL)	Average WBC Content
Whole blood	500	$1–2 \times 10^9$
Red blood cells	250	$10^8–10^9$
Washed red blood cells	180	$<5 \times 10^8$
Frozen deglycerolized red blood cells	250	$10^6–10^7$
Red blood cells, pheresis	300	$10^8–10^9$
Platelet concentrate (whole blood–derived)	50–75	4×10^7
Platelets, pheresis	200–500	$10^6–10^{8*}$
Fresh frozen plasma	220	$0.6 \times 10^6 – 1.5 \times 10^7$
Granulocytes, pheresis	220	$>1 \times 10^{10}$

*Less with new modified chambers.

Data from Brechner ME (ed). Technical Manual. Bethesda, Md., American Association of Blood Banks, 2005; Dzik WH. Leukoreduced blood components: Laboratory and clinical aspects. In Slonim TL, Dzik WH, Snyder EL, Stowell CP, Strauss RG (eds). Rossi's Principles of Transfusion Medicine, 3rd ed. Philadelphia, Lippincott, 2002, pp 270–287.

Table 28–3 Blood Components Requiring Irradiation for Patients at Risk of Graft-versus-Host Disease

Products *Known* to Contain Viable T Cells
Whole blood
Packed red blood cells (pRBCs)
Frozen/deglycerolized RBCs
Leukoreduced pRBCs
Platelet concentrates, pooled
Platelets, pheresis
Granulocytes
Nonfrozen plasma (fresh plasma)
Products That *May* Contain Viable T Cells
Fresh frozen plasma
Frozen plasma (e.g., FP24)
Products *Unlikely* to Contain Viable T Cells
Cryoprecipitate
SD-plasma
"Pathogen-reduced" products (in development)

through filtration may decrease the potential for GVHD and serve as an alternative to irradiation in the future when filtration technology is improved and questions about the minimum level of viable T cells that can lead to GVHD are resolved. However, there have been reports of TA-GVHD in patients who received leukoreduced but not irradiated RBCs, although the extent of leukoreduction was not uniformly quantified in such reports.[51–54]

Irradiated RBCs undergo enhanced efflux of potassium during storage at 1°C to 6°C,[55,56] which is not affected by prestorage leukoreduction.[57] Washing of RBC units before transfusion to reduce the supernatant potassium load is not typically warranted in most cases, because post-transfusion dilution prevents increases in plasma potassium.[58] On the other hand, when irradiated RBCs are used for neonatal exchange transfusion or the equivalent of a whole blood exchange is anticipated, RBC washing should be considered to prevent the possible adverse cardiotoxicity caused by hyperkalemia associated with irradiation and storage.[59] In this regard, recent studies have provided guidance on storage of irradiated and washed packed RBCs: storage at 4° C for 3 hours postirradiation and washing will produce units with less than 5 mEq of potassium per liter.[60]

Platelet components that have low levels of leukocytes because of apheresis collection or leukofiltration, or both, should also be irradiated if intended for transfusion to susceptible patients because, as with RBC transfusions, the minimum number of T cells that induces TA-GVHD has not yet been delineated.

In contrast, there is controversy about irradiation of fresh frozen plasma. It is generally accepted that the freezing and thawing processes destroy the T cells that are present in such plasma. However, two brief articles have suggested that immunocompetent progenitor cells may be present in frozen/thawed plasma, and the authors recommended that frozen/thawed plasma be irradiated.[61,62] Further studies are needed to validate these findings and to assess whether the number of immunocompetent cells present in thawed fresh frozen plasma is sufficient to induce TA-GVHD. In the rare instances in which nonfrozen plasma (termed *fresh plasma*) is transfused, it should certainly be irradiated because of the presence of a sizable number (approximately 1×10^7) of viable lymphocytes.

Blood components containing lymphocytes that are homozygous for an HLA haplotype that is shared with the recipient, whether that recipient is immunocompromised or immunocompetent, pose a specific risk for TA-GVHD. This circumstance occurs when first- and second-degree relatives serve as directed donors[10,11,37,39] and when HLA-matched platelet components donated by related or unrelated individuals are transfused.[63,64] Irradiation of blood components must be performed in these situations.

One group has evaluated lymphocyte cell surface activation markers over time to determine whether older red blood cells (4 days or more) had alterations that could account for the reduced frequency of TA-GVHD as compared with "fresh" blood transfusion. They demonstrated reduced expression of CD3, CD4, CD28, CD2, and CD45 and less responsiveness in a mixed lymphocyte culture (MLC) by day 4 of storage.[65] Additional studies are warranted, however, to confirm these findings using techniques more sensitive than MLC. In addition, the number and specific subtype of T cells present in a product that induce TA-GVHD may depend on the patient's immunocompetence at the time of transfusion. It is likely that the greater the degree of immunosuppression, the fewer viable T cells are required to produce GVHD in susceptible patients. It has also been suggested that CTLs or IL-2–secreting precursors of helper T cells may be more predictive of GVHD than the number of proliferating T cells alone.

Storage of Red Blood Cells and Platelets after Irradiation

RED BLOOD CELLS

Irradiation of RBCs is not a benign process. The viability in vivo of irradiated RBCs, evaluated as the 24-hour recovery, is reduced during storage compared with that of nonirradiated RBCs.[66–70] This reduced viability has raised questions concerning the maximum storage time for RBCs after irradiation. Davey and colleagues[66] found that the 24-hour recovery for RBCs preserved in a solution containing adenine, sodium chloride, dextrose, and mannitol (Adsol) and treated with 3000 cGy on day 0 was 68.5% ± 8.1% (mean ± standard deviation [SD]) after 42 days of storage compared with 78.4% ± 7.1% for control, nontreated RBCs. Subsequent studies employed total storage periods of 21 to 35 days after irradiation on day 0 or day 1. After storage for 35 days, the mean (± SD) 24-hour recovery for irradiated (3000 cGy) and control Adsol-preserved RBCs was 78.0% ± 6.8% and 81.8% ± 4.4%, respectively. In studies with a 28-day storage period, the values for irradiated (2500 cGy) and control Adsol-preserved RBCs were 78.6% ± 5.9% and 84.2% ± 5.l%, respectively.[68] In a study which compared x-ray to gamma-irradiation with CPDA1 red cells, slight increases in extracellular potassium were noted in gamma-irradiated cells with no differences in lymphocyte inhibition as measured by MLC; RBC survival and viability studies were not included in this report.[69]

Moroff and colleagues[70] evaluated the effect of irradiation on Adsol-preserved RBCs stored from day 1 to 28 (irradiated day 1, protocol 1), day 14 to 28 (irradiated day 14, protocol 2), day 14 to 42 (irradiated day 14, protocol 3), and day 26 to 28 (irradiated day 26, protocol 4). In comparison with previous work, these investigations were unique because RBCs were studied after being irradiated for various times in storage and then examined after further storage. For protocol 1,

the mean ± SD recovery was 84.2% ± 5.1% for control RBCs and 78.6% ± 5.9% for irradiated RBCs (n=16; P 0.01). With protocol 3, the recoveries were 76.3% ± 7.0% for control RBCs and 69.5% ± 8.6% for irradiated RBCs (n=16; P<0.01). Protocols 2 and 4 demonstrated comparable 24-hour recoveries for control and irradiated RBCs. Long-term RBC survival was comparable for control and irradiated RBCs in all protocols, confirming previous data showing that long-term survival of RBCs is minimally influenced by irradiation. On the basis of multiple linear regression analysis, only the length of storage after irradiation had a significant effect on the 24-hour recovery. No effect was related to day of irradiation or total storage time.

Most RBC properties such as adenosine triphosphate (ATP) levels and the amount of hemolysis were altered to only a small extent compared with control values with extended storage after irradiation, but potassium leakage from the RBCs during storage was substantially enhanced by irradiation.[70] Despite elevated potassium levels, the irradiation-induced changes in RBC viability and potassium leakage were not complementary. On the basis of analysis of these studies, FDA guidelines call for a 28-day maximum storage period for RBCs after irradiation, irrespective of the day of storage on which the treatment was performed, with the provision that the total storage time not exceed that for nonirradiated RBCs.[47]

The etiology of the RBC irradiation lesion has never been completely elucidated. Lipid peroxidation and RBC membrane protein array appear unaffected[71] whereas purine nucleotides decrease over time.[72] While the actual structural changes that make RBCs sensitive to irradiation-induced oxidative damage and result in potassium leakage are not yet clarified, addition of antioxidants such as dipyridamole, Trolox, and mannitol to RBCs prior to irradiation is under consideration in Japan.[73]

PLATELETS

In contrast to RBCs, platelets appear to be relatively unaffected by irradiation. The storage period at 20°C to 24°C for irradiated platelet components does not need to be modified. Neither in vitro nor in vivo platelet properties are influenced to any extent by irradiation. Many studies have confirmed that platelet properties are retained immediately after conventional levels of irradiation and at the conclusion of a 5-day storage period, whether irradiation is performed before storage or in the middle of storage.[74–81] One report, however, has indicated some differences in selected in vitro parameters between irradiated and control platelets after storage.[80]

Selection of Radiation Dose

In the past, there were no standards pertaining to the radiation dose that should be used. A survey in 1989 indicated that a range of radiation dose levels between 1500 and 5000 cGy (1 rad = 1 cGy) were being used, with the majority of facilities employing 1500 cGy.[82] These reported radiation doses were typically estimates and retrospective calculations because most facilities were not performing any type of dosimetry measurements. Furthermore, these values may be different from current values determined through careful dose mapping because there was previously no standardized way of calculating or reporting radiation dose. The selection of 1500 cGy as the target radiation dose was based on studies in the 1970s showing that 500 cGy abrogated the MLC response of isolated lymphocytes.[83–85]

Later studies from our laboratory with a more sensitive limiting dilution assay (LDA) indicated that 2500 cGy (measured at the internal midplane of a component) is the most appropriate dose.[86,87] In these experiments, RBC and platelet components were irradiated in their original plastic containers (blood bags) with increasing radiation doses. The author's laboratory selected LDA as a tool to study the effect of gamma-irradiation for several reasons. LDA measures the clonogenic potential of both CD4+ and CD8+ T cells in a functional assay. It provides a quantification at low T-cell numbers and has been used to determine residual, functional T cells in bone marrow purged of T cells, thus providing a clinical correlate of prevention of GVHD.[88] Assays of T-cell proliferation using MLC, mitogens, or detection of T cells by flow cytometry can detect up to a 2 logarithm (log) reduction in viable cells. PCR techniques are capable of detecting up to a 6-log reduction but cannot distinguish between viable and nonviable cells and hence are not informative if T cells are inactivated but remain in the sample. While the LDA assay may fail to detect an as yet undescribed human T-cell subset that contributes to GVHD, it is nonetheless an appropriate assay for selection of radiation doses for platelet pheresis and RBC components to abrogate TA-GVHD.

In the authors' studies, after each radiation dose, samples were removed and the clonogenic proliferation of T cells was measured by LDA. With RBC units, 500 cGy had a minimal influence, whereas 1500 cGy inactivated T-lymphocyte proliferation by approximately 4-log; however, some growth was still observed in each experiment. Increasing the dose to 2000 cGy resulted in no T-lymphocyte proliferation in all but one experiment. No proliferation was observed after 2500 cGy in any experiment.[86] In a subsequent study using platelet pheresis components with sufficient T cells to perform the LDA, the effects of 1500 and 2500 cGy were again evaluated.[87] With 1500 cGy, substantial inactivation was measured; however, some growth was still observed in all experiments. As noted with the RBC experiments, 2500 cGy resulted in complete abrogation of clonogenic T-lymphocyte proliferation. Other laboratories used more traditional assay methods to assess T-lymphocyte inactivation and suggested a radiation dose of between 2800 to 3000 cGy. Based on their review, the FDA has recommended that the irradiation process deliver 2500 cGy to the internal midplane of a freestanding irradiation instrument canister, with a minimum of 1500 cGy at any other point within the canister.[47]

Quality Assurance Measures

The instrument being used for irradiation must be documented to be operating appropriately and it must be confirmed that blood components have been irradiated. To ensure that the irradiation process is being conducted correctly, specific procedures are recommended for freestanding irradiators and linear accelerators, as summarized in Table 28-4 and discussed in detail in a published review.[89]

Dose mapping measures the delivery of irradiation within a simulated blood component or over an area in which a blood component is placed. This applies to a radiation field when a linear accelerator is used or to the canister of a freestanding irradiator. Dose mapping is the primary means of ensuring that the irradiation process is being conducted correctly. It documents that the intended dose of irradiation is being delivered at a specific location (such as the central midplane of a canister), and it describes the variation of the delivered radiation dose

Table 28–4 **Quality Assurance Guidelines for Irradiating Blood Components**

Dose
2500 cGy to the central midplane of a canister (freestanding irradiator) or to the center of an irradiation field (linear accelerator) with a minimum of 1500 cGy
Dose Mapping (Freestanding Irradiators)
Routinely, once a year (^{137}Cs) or twice a year (^{60}Co) and after major repairs, using a fully filled canister (water/plastic) with a dosimetry system to map the distribution of the absorbed dose
Dose Mapping (Linear Accelerators)
Yearly dose mapping with an ionization chamber and a water phantom recommended; more frequent evaluation of instrument conditions to ensure consistency of x-rays
Correction for Radioisotopic Decay
With ^{137}Cs as the source, annually With ^{60}Co as the source, quarterly
Turntable Rotation (Freestanding ^{137}Cs Irradiators)
Daily verification
Storage Time for Red Blood Cells after Irradiation
For up to 28 days; total storage time cannot exceed maximum storage time for unirradiated red blood cells
Storage Time for Platelets after Irradiation
No change related to irradiation procedure

Adapted from Moroff G, Luban NLC. The irradiation of blood and blood components to prevent graft-versus-host disease: Technical issues and guidelines. Transfus Med Rev 1997;11:15–26.

within a simulated component or over a given area. This allows conclusions to be drawn about the maximum and minimum doses being delivered. Dose mapping should be performed with sensitive dosimetry techniques. Several commercially available systems have been developed (see Dosimetry Systems in Use, below).

Other quality assurance measures include routine confirmation that the turntable is operating correctly (for ^{137}Cs irradiators), measurements to ensure that the timing device is accurate, and periodic lengthening of the radiation time to correct for source decay. With linear accelerators, it is necessary to measure the characteristics of the x-ray beam to ensure consistency of delivery. Confirming that a blood component has, in actuality, been irradiated is also an important part of a quality assurance program. Several firms have developed indicator labels for this purpose.

Dose Mapping with Freestanding Irradiators

For freestanding irradiators, a dose-mapping procedure measures the dose delivered throughout the circular canister in which the blood component is placed. To establish a two-dimensional map, a dosimetry system is placed in a canister that is completely filled with a blood/tissue-compatible phantom composed of water or an appropriate plastic such as polystyrene.[90,91] The dosimetry material is placed within the phantom in a predetermined way. This approach provides data showing the minimum levels of irradiation that would be absorbed by a blood component placed in the canister and recognizes that maximum attenuation occurs when the canister is completely filled with a blood-compatible material. The absorbed dose at the central midplane of a canister (i.e., at the center point) may be decreased by 25% (from 3100 to 2500 cGy) in a ^{137}Cs irradiator (JL Shepherd and Associates, San Francisco, Calif.) when the loading of the canister is changed from 0% (air) to 100% (with blood components).[92] An irradiation-sensitive film dosimetry system (International Specialty Products) was used in this study.

Other studies have shown that the variability in the dose delivered to the interior of simulated blood phantoms depended on the model of the ^{137}Cs freestanding irradiator.[93,94] An immobilized grid of thermoluminescent dosimeters in a plastic sheet was placed within the simulated blood units to measure dose delivery. A spacer in the bottom of the canister increased the minimum level of irradiation within the simulated blood units, as expected from the results of full-canister dose mapping involving a phantom.[94] The variability with ^{137}Cs irradiation is influenced by a number of factors, including the blood-compatible environment. Cumulatively, these studies underscored the need for consistency in loading the canister.

When an irradiator is purchased, the distributor provides a central dose level that is determined in a blood-compatible environment. In the 1970s and 1980s, manufacturers provided a central dose that was determined in air, resulting in the use of timer settings that provided a dose level somewhat less than was expected. Since the issuance of the FDA guidelines in July 1993 and the use of dose mapping, it has been necessary to readjust irradiation times with some instruments because the attenuation effect had not been considered previously.

The dose map can also be used to assess whether the turntable of a ^{137}Cs irradiator is rotating in an appropriate manner. The occurrence of comparable readings at the two edges of the two-dimensional map, as depicted in the theoretical dose map, indicates that the canister is rotating evenly in front of the ^{137}Cs source. If the turntable were not rotating, the dose levels at the edge of the map closest to the source would be much higher than those on the opposite edge (i.e., the side farthest from the source).

Dosimetry Systems in Use

The radiation dose delivered can be measured by a variety of dosimetry systems. Several commercial systems have been introduced to the market; each system consists of a phantom that fills the canister and a sensitive dosimeter. These

dosimeters are referred to as routine dosimeters. They are calibrated against standard systems, usually at national reference laboratories such as the National Institute of Standards and Technology in the United States. The routine dosimeter measurement systems were initially developed for use with ^{137}Cs irradiators because this is the predominant irradiation source for blood. Subsequently, they were also developed for use with ^{60}Co irradiators.

Thermoluminescent dosimeters (TLD chips) are one type of routine dosimeter. TLD chips are small plastic chips with millimeter dimensions having a crystal lattice that absorbs ionizing radiation. Specialized equipment is used to release and measure the energy absorbed by the TLD chip at the time of the test irradiation. In one commercially available system, chips are placed at nine different locations within a polystyrene phantom that fits into the canister for the IBL 437C irradiator (CIS US, Inc., Bedford, Mass.). The timer setting routinely used with the instrument is also used in the test procedure.

Two alternative systems use radiochromic film. On exposure to irradiation, the film darkens, resulting in an increase in optical density. The optical density, determined at various locations on the film, is linearly proportional to the absorbed radiation dose. Standard films that are irradiated at a given dose level with a source calibrated at a national reference laboratory provide the means to assess the absolute level of absorbed irradiation. This type of dosimeter is basically an x-ray film comparable with that used in clinical practice. With this device, the map that is developed identifies the absorbed radiation dose measured at a large number of locations.

In one such system, a film contained in a thin watertight casement is placed into the canister (International Specialty Products, Wayne, N.J.). This approach is being used with a variety of irradiators. The canister is filled completely with water before the irradiation procedure. This system provides a direct readout of the dose that is delivered throughout the canister. The timer setting used routinely is employed for the test procedure. In a second system, a film having different irradiation-sensitive characteristics is embedded between two halves of a circular-fitting polystyrene plastic phantom (Nordion International, Kanata, Ontario, Canada). Irradiation of specialized films is performed with a number of timer settings, each longer than that used routinely. The map produced is normalized for a central midplane dose of 2500 cGy. The time to produce the 2500 cGy is predetermined with a different dosimeter system, the Fricke system, in which absorbed radiation causes a change in the state of an iron salt that can be assessed spectrophotometrically.

Another approach to irradiation dose mapping employs a solid-state electronic dosimeter that is technically referred to as a metal oxide semiconductor field effect transistor (MOSFET). A board contains a number of small transistors in an arrangement that provides data for a dose map. The board is placed between two halves of a circular polystyrene phantom that fits into the canister. This dosimeter absorbs and stores the radiation dose imparted to it electronically. Irradiation causes the formation of holes in the metal oxide layer that become trapped within the transistor. The magnitude of the holes is evaluated by measuring the voltage across the transistor with a voltmeter. The voltages measured are converted to absorbed dose.

With each dosimetry system, measurements are used to express the absorbed radiation dose in grays (or centigrays).

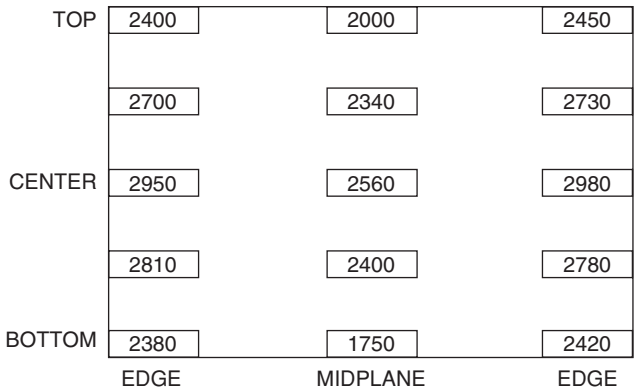

Figure 28–3 Two-dimensional dose map showing the irradiation dose distribution through a fully filled canister of a freestanding cesium 137 irradiator.

All dosimetry measurements are associated with a degree of uncertainty or possible error. The magnitude of the uncertainty depends on the kind of dosimeter used. For most dosimeters, the level is ±5% of the measured value. For a central absorbed dose level of 2560 cGy (see theoretical dose map in Fig. 28–3), the value could be as high as 2788 cGy or as low as 2432 cGy. Correspondingly, a measured value of 2400 cGy could be as high as 2520 cGy or as low as 2380 cGy. Because the measured value could in actuality meet the 2500 cGy standard, it is appropriate to accept a value of 2400 cGy as meeting the current standard. The same approach should be used when evaluating the minimum value on a dose map. Albeit arbitrary and cautious, the actual minimum on an irradiation dose map should not be below 1500 cGy.

Other Measures with Freestanding Irradiators

CORRECTION FOR ISOTOPIC DECAY

It is important to lengthen the time of irradiation periodically to correct for decay of the isotopic source that emits the gamma-irradiation. Previously, this was the only major quality assurance measure that was performed routinely. With the 30-year half-life of ^{137}Cs, annual lengthening of the timer setting is appropriate. On the other hand, since the half-life of ^{60}Co is only 5 years, the time of irradiation should be increased on a quarterly basis. The additional seconds of irradiation that are needed can be calculated using formulas that can be found in a physics textbook. Alternatively, distributors of irradiators provide a chart that specifies the appropriate setting as a function of calendar time.

TURNTABLE ROTATION

For ^{137}Cs irradiators, it is essential that the turntable operate at a constant speed in a circular pattern to ensure that all parts of a blood component are exposed equally to the source. Daily verification of turntable rotation is an appropriate quality assurance measure. With some freestanding irradiator models, rotation of the turntable can be observed before the door of the compartment in which the canister is positioned is closed. In other models, it can be observed only indirectly by ensuring that an indicator light is operating appropriately. With some older models, there have been occasional reports that the turntable failed to rotate because of mechanical problems. Such problems should not be encountered with the newer models because of changes in the turntable mechanisms.

ASSESSING RADIOACTIVITY LEAKAGE

Irradiators are constructed so that the isotopic sources are contained in a chamber heavily lined with a protective lead shield to prevent leakage of radioactivity. Accordingly, gamma-irradiators are considered to be safe instruments. Although there have been no reports of source leakage of radioactivity, periodic measurements are warranted. Attaching a film badge to the outside of the irradiator, using a Geiger counter periodically, and performing a wipe test of the inside of the chamber where the canister is positioned at least semiannually are typical measures.

Dose Mapping with Linear Accelerators

Linear accelerators that are used to provide radiation therapy are carefully monitored to ensure appropriateness of dose to an irradiation field. When blood components are treated with x-rays, the instrument settings are different from those used to treat oncology patients. Hence, additional periodic quality control measures, primarily to assess the dose delivered to blood components, are needed to ensure that linear accelerators are being operated appropriately when used for blood irradiation.

Currently, there are no commercially available systems for assessing the dose delivered throughout the area of an irradiation field in which blood components are placed for treatment with x-rays. An ideal dosimeter for this purpose would be made of a tissue-compatible plastic phantom containing appropriate dosimeter material that could be placed at the correct distance from the source. An alternative approach might involve use of a blood bag filled with water (simulating a blood unit) containing TLD chips, as described earlier. In comparative studies using such simulated blood units, it was determined that radiation delivery was more uniform with linear accelerators than with ^{137}Cs freestanding irradiators.[93] This uniformity reflects the relative homogeneity of x-ray beams. One group of investigators has developed a phantom with TLD chips that can serve as both a dose monitor and a temperature monitor, a critical issue when multiple units are held out of refrigeration during irradiation.[95]

In the absence of an available system modified for irradiation of blood bags, the dose delivered throughout an irradiation field should be mapped with the dosimetric measuring system known as an ionization chamber. The ionization chamber is used to calibrate linear accelerators for use with patients. In addition, on a yearly basis, dose mapping should be performed using a tissue-compatible phantom. In view of the widely divergent conditions that are employed during the operation of linear accelerators, other parameters pertaining to the x-ray beam should be evaluated on at least a quarterly basis to provide assurance that the instrument is being used appropriately for the irradiation of blood components.

When setting a linear accelerator for blood component irradiation, the following should be measured: (1) the distance between the x-ray source and the position where the blood components are to be placed, (2) consistency of the strength of the x-ray beam, and (3) intensity of the x-ray beam. The distance between the source and position on the table where blood components will be placed (referred to as the target) can be evaluated easily with a calibrated measuring device. This is a simple task that can be performed routinely. The consistency of beam output can be evaluated by measuring the beam current. Beam intensity can be evaluated by measuring the ionization current in a monitoring ionization chamber array, which can be expressed in terms of the number of photons delivered per square centimeter. These parameters should be assessed routinely as part of quality control programs used by radiation physicists. A code of blood practice was published in 1994 by the Radiation Therapy Committee of the American Association of Physicists in Medicine for the quality control of radiotherapy accelerators.[96,97]

Unusual Geometries

Dose delivery can be influenced by several physical and geometrical factors. The greatest influence on delivery is the geometry of the sample being irradiated. The authors' laboratory used gel dosimetry to measure three-dimensional radiation dose distributions in blood containers with irregular geometries, such as syringes, platelet bags, and small-volume red cell bags.[98] This approach, while technically complex, permits "imaging" of the actual dose delivered.

Confirmation That Irradiation Occurred

It is important to have positive confirmation that the irradiation process has taken place. For example, irradiation would not occur if an operator failed to initiate the electronically controlled irradiation process or there was an instrumentation malfunction. A radiation-sensitive indicator label has been developed specifically for this purpose (International Specialty Products, Wayne, N.J.). The label containing a radiation-sensitive filmstrip is placed on the external surface of the blood component. Irradiation causes distinct visually observable changes in the label that can be readily assessed by the operator, which represents a permanent visual record that the irradiation process has taken place. The reliability of this type of indicator has been documented in a multisite study.[99]

Two versions of the indicator label have been manufactured. They differ in the range of irradiation needed to cause a change in the radiation-sensitive film. The ratings for these indicators are 1500 and 2500 cGy. The ratings serve as an approximate guideline for the amount of absorbed radiation needed to change the window completely from reddish to opaque. Because the indicator labels are designed and used to confirm that the irradiation process has occurred, the authors' laboratory utilizes the 1500 cGy label as the most appropriate tool to perform this quality control measure. This is based on the routinely observed pattern of dose distribution to a blood component in a canister of a freestanding irradiator. Despite a targeted central dose of 2500 cGy, there are spots at which the dose is less. If the theoretical dose map presented in Figure 28–3 is used as an example, there is a spot that receives only 1800 cGy. If the label rated 2500 cGy was located on the external surface of a component, there might be minimal changes in the appearance of the radiation-sensitive film window. This would result in a judgment that the blood component was not irradiated when in actuality it was treated satisfactorily.

New Methods

Photochemical treatment (PCT) using psoralens and long-wavelength UV irradiation (UVA) have been developed to reduce the risks of bacterial and viral contaminants of platelet transfusions (see Chapter 27 for further discussion of pathogen inactivation technologies). Psoralens bind reversibly to nucleic acids by intercalation and, after UVA illumination, form covalent monoadducts and crosslinks with RNA and DNA. The process modifies bacterial and viral genomes sufficiently to

prevent replication. Among a broad group of compounds, the psoralen S-59 has been shown to be particularly effective in inactivating bacteria and viruses without adversely affecting platelet function in vitro and in vivo.[100] Clinical trials confirm adequate in vivo survival, lack of adverse effects, and equivalence to standard platelet units.[101]

The use of S-59 and PCT has been studied for possible inactivation of leukocytes in platelet concentrates.[102,103] PCT inactivation of T cells was evaluated with four assay systems. These included T-cell quantitation, inhibition of cytokine synthesis, modification of leukocyte genomic DNA by quantification of psoralen-DNA adducts, and inhibition of replication of T cells using PCR amplification of genomic DNA sequences. This work built on previous studies in which IL-8, a marker of cytokine generation in platelet concentrates, was significantly reduced in pools treated with PCT compared with those treated with irradiation.[102,103]

A more detailed study by Grass and coworkers[103] compared PCT with irradiation at 2500 cGy; cytokine synthesis was not inhibited, and induction of DNA strand breaking was inhibited less than with S-59 and PCT. LDA was used to confirm inactivation of T cells in the platelet concentrates. The efficacy of S-59 and PCT was further supported by a study of transfusion-induced GVHD in a murine F1 hybrid model.[104,105] No GVHD was noted in mice receiving splenocytes treated with either 2500 cGy or S-59 at 150 µmol/L and UVA at 2.1 J/cm. Another set of experiments was performed to study the use of PCT to prevent GVHD in an immunocompromised mouse model.[106] Taken together, these studies suggest that PCT may well be an alternative to irradiation and may provide a mechanism to prevent an increase in cytokine concentration in platelet concentrates. The limitation of PCT methodology is the need for UVA penetration, which is not currently possible with RBC products.

Chapter 29

Washed and Volume-Reduced Blood Components

S. Gerald Sandler • Viviana V. Johnson • Jayashree Ramasethu

INTRODUCTION

Standard red blood cell (RBC) or platelet components may be washed or volume-reduced to make them more suitable for patients who have special transfusion requirements. In the United States, blood components for transfusion are standardized to comply with applicable federal statutes and regulations of the Food and Drug Administration (FDA).[1] Typically, community blood centers collect blood from donors and supply hospital transfusion services with standard FDA-licensed blood components. Some hospital transfusion services modify RBC or platelet components by washing with 0.9% sodium chloride ("normal saline") or by centrifugation to reduce the volume of plasma or anticoagulant-preservative solution. While the rationale for transfusing these modified blood components in selected recipients may be medically sound, the methods for their preparation are often not standardized and their therapeutic efficacy is not well established.

Washed or volume-reduced blood components may be considered to be the latest step in the process of improving the match between the blood products that are collected from donors and the products that are needed by individual patients. In 1937, two decades after the introduction of blood transfusions of stored whole blood,[2] concentrated RBCs were introduced as an alternative to whole blood for anemic patients who were at risk for hypervolemia.[2,3] Early experience transfusing concentrated RBC components established lower rates of adverse transfusion reactions compared with conventional whole blood.[4] The subsequent development of sterile plastic collection bags and refrigerated centrifuges facilitated the separation of whole blood collections into RBC, plasma, and platelet components. This advance made it possible to match standardized blood components to *categories* of patients, but these generic blood components did not always meet the requirements of *individual* patients. The introduction of washed or volume-reduced blood components allowed physicians to further customize blood transfusions for the requirements of specific patients.

The following chapter summarizes current indications and methods for preparing washed or volume-reduced RBC and platelet components. The methods for preparing the modified blood components may vary in technical detail, depending on the specific RBC or platelet component selected for washing or volume reduction. In this chapter, the generic term RBC component applies to all RBC-containing components that are categorized as Red Blood Cells in the FDA-approved Circular of Information.[1] The term platelet component applies to either Platelets (random donor platelet concentrates) or Platelets Pheresis (apheresis platelets), as described in the Circular of Information.[1]

WASHED RED BLOOD CELLS

Transfusion services may wash standard RBC components using automated cell washing systems to prepare Washed Red Blood Cells for selected patients. This procedure decreases their risk of adverse effects from constituents of plasma (i.e., plasma proteins, antibodies, electrolytes), from constituents of anticoagulant-preservative-storage solutions (i.e., citrate, adenine, dextrose, mannitol), and from glycerol, which is occasionally used to freeze RBC units (Table 29–1). Washing RBC components removes approximately 90% of leukocytes, 20% to 90% of platelets, and nearly all plasma proteins, including unwanted donor antibodies.[5] In many situations, RBC components are washed to decrease the potassium concentration or remove potentially allergenic plasma proteins. During intraoperative salvage of shed blood, recovered RBCs are washed to remove clots, leukocytes, platelets, cellular debris, and heparin. Previously, RBC components were routinely washed before transfusion in patients with paroxysmal nocturnal hemoglobinuria (PNH), but recent studies demonstrate that this precaution is unnecessary (see below).

Indications for Washed Red Blood Cells

Large-Volume or Rapid Transfusion to Newborns and Other Small Children

Small-volume transfusions (<25 mL/kg) of CPDA-1"packed" RBC components or RBC components in extended-storage media (AS-1 [ADSOL]; Baxter Healthcare Corporation, Deerfield, Ill.; AS-3 [Nutricel]; Medsep Corporation, Covina, Calif.; AS-5 [Optisol]; Terumo Corporation, Somerset, N.J.) may be safely transfused to small children, including newborns and preterm infants.[6] However, large-volume transfusions (>25 mL/kg) of conventionally stored RBC components, particularly if transfused rapidly, may cause acute hyperkalemia, cardiac arrest, and death.[7] During refrigerated storage of RBC components, potassium leaks from the intracellular fluid of RBCs, increasing potassium concentration in the plasma (or in the anticoagulant-preservative solution) to levels that are potentially dangerous for rapid transfusions in susceptible recipients.

Table 29–1 **Clinical Indications and Rationale for Washed RBC Components**

Clinical Indication	Rationale
Large-volume or rapid transfusion	Particularly in newborns and small children, decreases risk of hyperkalemia and cardiac arrhythmias
Following gamma irradiation and storage	Decreases potassium in plasma or additive solution
Allergic or anaphylactic reaction	Removes allergenic plasma proteins, whether or not they are specifically identified
Intraoperative salvaged autologous blood	Removes clots, cellular debris, and heparin and suspends shed RBCs in saline solution
T-activation	During ongoing hemolysis, reduces further hemolysis by eliminating IgM anti-T present in normal donors' plasma
Paroxysmal nocturnal hemoglobinuria	No longer recommended

The potassium concentration in plasma of CPDA-1 RBC components increases from 4.2 mmol/L to nearly 80 mmol/L during the 35-day storage period.[6] For a 1-kg newborn, a conventional transfusion (15 mL/kg) of 42-day stored AS-1 RBCs (hematocrit of 80%) may have a potassium *concentration* as high as 50 mEq/L, but the *total potassium content* is only 0.15 mEq. While that relatively high concentration of potassium is tolerable and safe if the component is transfused slowly (over 2 to 4 hours), the same component could present a potentially fatal acute potassium load if transfused rapidly in a small child or susceptible adult. Rapid transfusions of stored RBC components in such patients may increase potassium acutely and, therefore, require washed or freshly collected RBC components. Typical situations include exchange transfusions, extracorporeal membrane oxygenation (ECMO), cardiopulmonary bypass, or solid organ transplantation.[8–10] Washed RBC components should also be considered for large-volume (>25 mL/kg) or rapid transfusions in newborns and other small children with renal failure, hyperkalemia, or severe acidosis.

Some physicians are also concerned that the doses of certain additives in extended-storage solutions (AS-1, AS-3, AS-5) may exceed known limits for safety for large-volume transfusions in small children.[11] These concerns derive from the theoretical possibility that constituents in the storage media could contribute to hyperosmolality, hyperglycemia, hypernatremia, or hyperphosphatemia. For that reason, some transfusion services routinely wash or volume-reduce RBC components stored in additive solutions for large-volume or rapid transfusions in newborns or other small children.

Transfusion of RBC Components following Gamma Irradiation

To prevent transfusion-associated graft-versus-host disease (TA-GVHD) in immunocompromised or other patients who are at risk, transfusion services (or blood centers) routinely gamma-irradiate blood components with a dose of 2000 to 3000 cGy. Although gamma-irradiation is highly effective for preventing TA-GVHD, irradiation has adverse effects on RBC survival, plasma hemoglobin concentration, and RBC ATP.[12–15] Plasma potassium concentration nearly doubles during the 48 hours after RBC components are irradiated with 3000 cGy.[12] Gamma-irradiation increases passive permeability of RBC membrane lipid bilayers, resulting in a progressive, reciprocal increase in intracellular sodium and decrease in intracellular potassium.[13] AABB *Standards* requires RBC components to outdate no longer than 28 days from the date of irradiation.[16] While washing irradiated RBC components reduces potassium concentration in the supernatant, it does not arrest the process. From the time irradiated RBC components are stored following washing, potassium concentration increases in a time-dependent fashion, which is more rapid than for nonirradiated RBC components. The potassium concentration in irradiated and washed RBC components may reach a critical concentration of 5 mEq/L after only 3 hours of storage at 4°C, compared with 6 hours for nonirradiated washed RBC components.[17]

Allergic or Anaphylactic Reactions

Mild, first-time allergic transfusion reactions (hives, flushing, pruritus) often seem to be *product*-related, rather than *patient*-related. These reactions typically respond to antihistamines and do not recur when additional plasma-containing blood components are transfused. In contrast, some chronically transfused persons develop more serious and generalized allergic reactions (bronchospasm, rash, nausea, vomiting, or diarrhea) that are not prevented by, or respond to, treatment with antihistamines. Transfusing washed RBC components usually prevents allergic reactions in such patients.

If acute allergic reactions progress to life-threatening anaphylaxis, bronchospasm, and hypotension, a diagnosis of an immunoglobulin A (IGA) anaphylactic reaction should be considered.[18] Conventionally, that diagnosis is made by demonstrating IGA deficiency (by a highly sensitive passive hemagglutination inhibition assay) and the presence of anti-IgA (by passive hemagglutination assay).[19] However, we advise caution when interpreting results of IgA hemagglutination assays because they may yield nonspecific results.[20] The same hemagglutination assay that is used to diagnose *patients* with IgA anaphylactic reactions detected IgA deficiency and the presence of anti-IgA in 1:1200 asymptomatic healthy *blood donors.*[19] Clearly, this number of healthy persons at risk for an IgA anaphylactic reaction greatly exceeds the incidence of IgA anaphylactic transfusion reactions in clinical practice. Nonetheless, if the diagnosis of IgA deficiency is made, RBCs and platelets can be washed with high volumes of saline (4–6 L) to effectively remove plasma antibodies. Washed RBC and platelet components have been transfused successfully in persons with IgA deficiency and anti-IgA who had a history of anaphylactic transfusion reactions when blood components from IgA-deficient donors were not available.[21,22] Other severe generalized reactions to plasma-containing blood components that may be abrogated by washing components prior to transfusion include transfusion-related acute lung injury (TRALI), leukocyte-mediated cytokine reactions, and anaphylaxis in persons with ahaptoglobinemia and antihaptoglobin.[23]

Intraoperative Salvage of Shed RBCs

Intraoperative salvage of shed RBCs has been used for more than four decades to reduce the number of allogeneic blood transfusions in trauma and surgery associated with large-volume blood loss.[24–26] Typically, shed blood is aspirated from the sterile surgical field, anticoagulated using a heparin-saline solution, and washed with 0.9% sodium chloride in an automated cell salvage machine. The effluent containing clots, leukocytes, platelets, cellular debris, and heparin is discarded. Saline-washed concentrated autologous RBCs are returned to the patient. When suitable wash volumes are used, activated coagulation factors, cytokines, and heparin are substantially reduced.[27–32]

An alternative method of salvaging shed autologous RBCs involves collecting heparinized sanguineous drainage from the chest, large joints, or other sites that is returned directly (unwashed) from collection canisters.[33–36] Postoperative infusion of unwashed filtered blood has been reported to be effective and without clinically relevant complications in orthopedic patients.[33,34] However, this method is controversial, because such drainage may contain procoagulant material, variable amounts of anticoagulant, and unsterile debris.[35] Even *saline-washed* salvaged RBCs collected under optimal conditions may contain residual biologically active materials capable of causing increased vascular permeability, acute respiratory distress syndrome, or disseminated intravascular coagulation.[36,37] These complications, which have been described as the "salvaged blood syndrome," can be averted by standardizing aspiration methods, controlling saline wash volumes, and monitoring for an abnormal accumulation of debris on the inner wall of the rotating bowl.[36]

T-Activation of RBCs

Immune-mediated hemolysis has been reported following transfusion of plasma-containing blood components to patients whose RBC T-crypt antigens have been exposed by bacterial infection.[38–40] T-activation occurs when bacterial neuraminidase removes *N*-acetyl neuraminic acid and exposes RBC T-crypt antigens. Exposed T-crypt antigens bind with IgM anti-T, a normal constituent of adult plasma, resulting in RBC agglutination (polyagglutination) and hemolysis. T-activation has been reported to occur in a wide range of bacterial infections, including necrotizing enterocolitis, septicemia, hemolytic uremic syndrome, and *Streptococcus pneumoniae* infection. T-activation should be suspected in children who have the onset of intravascular hemolysis following transfusion of plasma-containing blood components.

T-activation has been diagnosed less frequently in recent years because many hospital transfusion services now use non-plasma-containing monoclonal typing reagents instead of traditional plasma-derived blood typing reagents (anti-A, -B, and -A,B). Previously, some cases of clinically unrecognized polyagglutination due to T-activation were detected during routine compatibility testing using plasma-derived ABO typing reagents. Discrepancies in forward and reverse ABO typing results caused by polyagglutination or in vitro hemolysis suggested T-activation. T-activation is confirmed by specific agglutination tests using *Arachis hypogaea* and *Glycine soja* lectins. To prevent further hemolysis in patients who have active hemolysis and polyhemagglutination, RBC (or platelet) components should be washed using 0.9% sodium chloride before transfusion. Exchange transfusion with plasma-reduced components may be necessary for infants with T-activation and ongoing hemolysis.[39]

In patients with T-activation, some physicians recommend completely avoiding transfusions of fresh frozen plasma, platelets, or other plasma-containing blood products. Others question the clinical importance of T-activation and recommend that if plasma-containing components are indicated, they should not be withheld.[41] Recommendations, which are based on case reports, are conflicting and there are neither evidenced-based guidelines nor results of a randomized, controlled clinical trial to direct practice. The authors concur with the preponderance of clinical evidence, which favors not withholding plasma-containing blood components when they are indicated. The authors do not recommend that transfusion services, which routinely use murine or other monoclonal blood typing reagents, consider adding human plasma–derived typing reagents as a screening procedure to detect T-activation.

Paroxysmal Nocturnal Hemoglobinuria

PNH is an uncommon stem cell disorder manifested by complement-mediated hemolytic anemia, thrombophilia, and marrow failure.[42–44] The mainstay of managing the typical Coombs-negative, treatment-resistant, intravascular hemolytic anemia is RBC transfusions.[45] Promising results have been reported for managing hemolysis using eculizumab, a humanized monoclonal antibody to complement C5.[46] However, the role for this new treatment has yet to be defined.

In 1948, Dacie reported that blood transfusions exacerbated complement-mediated intravascular hemolysis in patients with PNH, increasing hemoglobinuria and hemoglobinemia.[47] As a consequence, some hematologists request washed RBC components for routine transfusions in patients with PNH. Admittedly, post-transfusion hemolysis is rare in patients with PNH when washed RBC components are transfused,[47] although it has been reported.[48,49] However, it should be noted that most PNH patients do not experience hemolysis after RBC transfusions, even when whole blood is transfused.[50] A retrospective review of 23 PNH patients who were transfused with a total of 556 units of whole blood, packed RBCs, leukocyte-poor RBCs, washed RBCs, frozen RBCs, and intraoperatively salvaged RBCs, identified only one case of post-transfusion hemolysis.[51] This case occurred after transfusion of group O whole blood to a group AB-positive recipient. This specific serologic incompatibility is similar to that in the 1948 case reported by Dacie, which is the origin of the practice of washing RBC components before transfusion to patients with PNH.[47] Based on this large-scale study, a supporting opinion from the PNH Interest Group,[52] as well as the authors' own uneventful personal experiences transfusing patients with PNH with unwashed AS-1 RBCs, we believe that transfusing washed RBC components to PNH patients is unwarranted.

Methods for Preparing Washed Red Blood Cells

RBC components may be washed manually using a refrigerated centrifuge or, more commonly, an automated cell washer. Washing an RBC component using 1 to 2 L of 0.9% sodium chloride removes approximately 99% of plasma proteins, electrolytes, and antibodies but may result in loss of up to 20% of the RBCs depending on the protocol.[53] Rarely,

recipients who have acute reactions to even small quantities of residual plasma require RBC components that have been washed using 4 to 6 L of saline. If the objective of washing is to remove leukocytes, platelets, and plasma, the cell washer may be programmed to remove the buffy coat, which will increase loss of RBCs. If RBC components are already leukocyte-reduced prior to washing, there is no requirement to remove the buffy coat and RBC loss will be minimized. Most transfusion services use cell washers with an "open" system, which limits the duration of refrigerated storage (1°C–6°C) to 24 hours.

Alternatives to Washed Red Blood Cells

For certain clinical situations, there may be alternatives to washed RBC components for reducing the potassium concentration or removing plasma proteins. For rapid transfusions in small infants, reconstituted whole blood (i.e., RBCs resuspended in fresh-frozen plasma shortly before transfusion), should dilute supernatant potassium to a safe concentration. According to the AABB Pediatric Hemotherapy Committee, "reconstituted whole blood…or whole blood (<5 days old) may be given [to infants and children <18 years] without the need for further justification in the setting of massive transfusions."[54]

Additionally, selecting an RBC component stored in AS-1, AS-3, or AS-5 preservative-storage solutions, rather than as packed CPDA-1–anticoagulated RBCs in plasma, should reduce the *concentration* of plasma proteins to a level tolerable for most patients with mild, recurrent allergic reactions.

VOLUME-REDUCED RED BLOOD CELL COMPONENTS

Hospital transfusion services may prepare volume-reduced RBC components for newborns or other small children who require transfusions but whose capacity to receive additional intravenous fluids is limited. Volume-reduction methods are intended primarily for AS-1 and AS-3 RBC components (hematocrit 60%) because "packed" CPDA-1 RBC components (hematocrit 75% to 80%) are already concentrated.

Indications for Volume-Reduced RBC Components

Volume-reduced RBC components are indicated when the intended recipient has a need for RBC transfusion (e.g., symptomatic anemia), but the patient's circulatory system cannot tolerate the additional volume. In adults, this situation may be the consequence of renal or cardiac insufficiency. In newborns, it may result from competition between intravenous nutrition protocols, medications, and blood components for the relatively small volume that the infant's circulation can tolerate. Transfusion of volume-reduced RBC components in volume-sensitive infants and small children is controversial. Not all physicians agree that recentrifugation of conventional RBC components with additive solutions (hematocrit 60%) to prepare volume-reduced RBCs (hematocrit 85% to 87%) is a clinically meaningful procedure. Alternatives to volume-reduction of RBC components include transfusing less volume or selecting ("packed") CPDA-1 RBC components, which have a higher hematocrit.

Methods for Preparing Volume-Reduced Red Blood Cells

AS-3 Red Blood Cells

Conventional Red Blood Cells are prepared by removing supernatant plasma from Whole Blood following a "heavy spin" (5000 × *g*, 5 minutes).[55] Removing 225–250 mL of plasma results in an RBC component with a hematocrit of 70% to 80%. The hematocrit of the final component may be decreased by removing proportionally less plasma.[55] Strauss and colleagues developed a method to prepare multiple aliquots of RBCs for neonatal transfusions with hematocrit >90% using RBC components stored at 4°C for as long as 42 days.[56] For this method, donor blood is collected in a primary bag containing CP2D anticoagulant (Leukotrap RC System, Miles Inc., Elkhart, Ind.), which is centrifuged at 5000 × *g* for 5 minutes. Platelet-rich plasma is transferred to a second bag, which is disconnected. Extended storage media (100 mL) (Nutricel, AS-3, Miles) is added to the storage bag, and after mixing, the RBCs are transferred via the leukocyte-reduction filter to another storage bag. A cluster of small-volume bags is attached to the storage bag using a sterile connecting device. When a transfusion is ordered, the storage bag is centrifuged in an inverted position to pack the AS-3 RBC component to a hematocrit of approximately 90%. Strauss modified the original method to centrifuge at 4000 × *g* for 4 minutes, not faster as in the original description.[57] The volume of RBCs requested flows from the bottom of the storage bag through the outlet tubing into one of the small-volume bags. The aliquot is disconnected, and the residual contents of the storage bag are mixed thoroughly and returned to storage until the next aliquot is required. During storage, AS-3 RBCs are mixed and resuspended weekly. In the original study, measurements of extracellular potassium, hemoglobin, and lactic dehydrogenase from repeatedly mixed and centrifuged units that were stored in inverted position were comparable to those of uncentrifuged, conventionally stored AS-3 RBCs.[56]

AS-1 Red Blood Cells

The method described above for AS-3 RBC components has been modified to prepare AS-1 RBC components with hematocrits of approximately 85% to 87% after storage at 4°C for as long as 42 days.[58] For this method, AS-1 RBC components (Adsol, Baxter Healthcare Corp., Deerfield, Ill.) are processed and stored by conventional methods with hematocrits of approximately 60%. When a transfusion is requested, the AS-1 RBC component is centrifuged in an inverted position at 4000 × *g* for 4 minutes. Aliquots are removed, as above. During storage, the primary AS-1 RBC component is remixed and stored until another transfusion is ordered and aliquots are removed. We concur with the authors of this method, who caution that "… this technique may not be desired by all centers, and if it is adopted, quality control studies should be performed to ensure the quality and sterility of the RBC aliquots."[58]

Inverted Gravity Sedimentation

Storing RBC components in the refrigerator "upside down" (inverted gravity sedimentation) will concentrate AS-1 RBC components to a hematocrit of approximately 68% by 72 hours.[59] This simple manipulation provides a method for volume-reducing AS-1 RBC components in transfusion services that may not have access to an appropriate refrigerated centrifuge.

WASHED PLATELET COMPONENTS

Washed platelet components contain less plasma, but the procedure also decreases the total platelet content and may decrease platelet function. Therefore, washing platelet components is not recommended, except for relatively limited clinical indications[60] (Table 29–2).

Indications for Washed Platelet Components

Recurrent Allergic or Anaphylactic Transfusion Reactions

Patients who require washed RBC components because of recurrent allergic or anaphylactic transfusion reactions may also require washed platelet components (see above).

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is a potentially fatal disease of the fetus or newborn that may occur when there is serologic incompatibility for human platelet antigens (HPAs) between mother and fetus. More than 16 different HPAs have been implicated in NAIT.[61] Approximately 90% of cases of NAIT in Caucasians of European ancestry present in an HPA-1a–positive newborn or fetus of an HPA-1a–negative mother who has developed anti-HPA-1a.[62] Approximately 6% to 19% of cases of NAIT in Caucasians are due to anti-HPA-5b and 0% to 2% are due to anti-HPA-1b.[63,64] Mothers of Asian ancestry whose newborns have NAIT most often have antibodies specific for HPA-4 antigens.[65]

One approach to managing an at-risk pregnancy consists of using periumbilical blood sampling (PUBS) to monitor fetal platelet counts after 20 weeks of gestation and infusing the mother with intravenous immune globulin (IVIG) (1 g/kg) weekly to decrease the risk of fetal thrombocytopenia.[66] In this protocol, adding dexamethasone (1.5 mg) to weekly infusions of IVIG did not improve the response rate. In an alternative approach, the fetus's platelet count is measured at 20 weeks of gestation and the mother receives weekly infusions of IVIG (1 mg/kg) if the fetus is thrombocytopenic.[67] A second PUBS is performed at 26 weeks, and if the fetus remains thrombocytopenic, prednisone (60 mg daily) is added to weekly IVIG infusions. PUBS is repeated before delivery and, if thrombocytopenic, the fetus is transfused with platelets.[67]

Since maternal platelets are serologically compatible with the offending antibody in NAIT, the mother is a potential source of platelets for transfusion in the newborn.[68] However, maternal platelets are collected in the mother's plasma, which contains the offending antibody. Therefore, it is necessary to wash the maternal platelet component and resuspend the maternal platelets in compatible plasma, 0.9% sodium chloride, or a platelet storage solution. Platelet components may be washed by manual or automated methods using 0.9% sodium chloride, with or without adding ACD-A.[69] Such washing may result in loss of as many as 33% of the original platelets.[70] Since washing presently requires an "open" system, and since platelets must be stored at 20°C to 24°C, washed platelet components must be transfused within 4 hours.

A limited number of blood centers are able to supply HPA-matched platelet components collected from HPA-typed and qualified donors.[70] Usually, the donor panels are limited to HPA-1a–negative platelet donors, since this is the most frequently required HPA phenotype. In some blood centers, these platelet donors are scheduled for platelet apheresis collections at frequent intervals, so that their platelet components qualify for "emergency release" protocols (provided that recent test results are acceptable). In the authors' experience, serologically compatible platelet components collected from such call-in donors may be collected and emergency-released faster than collecting, testing, and processing platelet components from the postpartum mother. Donors of less common HPA phenotypes are more difficult to identify and recruit. When maternal platelets or HPA-matched platelets from allogeneic donors are transfused, conventional doses of platelets (10 mL/kg) should be adequate for most clinical situations. Nevertheless, monitoring post-transfusion platelet counts is essential, given the serious consequences of inadequate dosing in thrombocytopenic newborns.

Out-of-Group Platelet Components

In many hospitals, platelet components from group O donors are transfused to group A, B, or AB recipients if ABO group-specific platelet components are not available. Usually, the small volume of donor plasma, representing a "minor-type" ABO incompatibility, does not cause overt hemolysis. Recipients of out-of-group platelet transfusions may develop a weakly positive direct antiglobulin test result, but that is typically the only evidence of incompatibility. Occasionally,

Table 29–2 **Clinical Indications and Rationale for Washed Platelet Components**

Clinical Indication	Rationale
Allergic or anaphylactic reactions	Removes allergenic plasma proteins, whether or not they have been specifically identified
Febrile nonhemolytic transfusion reactions	May be effective in some adults but unproved in children
Neonatal alloimmune thrombocytopenia	Removes maternal alloantibodies from platelet components collected from the mother, whether or not serologic specificity has been identified
Out-of-group platelets	Eliminates risk of hemolysis due to anti-A or -B when compatible platelet components are not available for susceptible progenitor cell transplantation or newborn recipients
T-activation	During ongoing hemolysis, reduces further hemolysis by eliminating IgM anti-T present in normal donors' plasma
Paroxysmal nocturnal hemoglobinuria	No longer recommended

acute intravascular hemolysis may occur (e.g., when ABO-incompatible apheresis platelet components from donors who have high-titer anti-A/A,B have been transfused to A_1 recipients).[71,72] As clinical practice shifts from transfusing pools of random donor platelet concentrates (where a high-titer unit is diluted) to transfusing more single-donor (apheresis) platelet components,[71] more cases of hemolysis may be identified. Some transfusion services perform anti-A/anti-A,B titers on group O single-donor platelet components prior to an "out-of-group" transfusion.[73] However, there is lack of agreement as to what titer is clinically relevant and whether IgM or IgG antibody is more significant.[73] Although washing of out-of-group platelet components removes incompatible plasma, the process may decrease platelet function,[74] requires considerable skill and experience,[59] and is not practiced routinely.

In some hospitals, the practice of washing (or volume-reducing) platelet components to prevent anti-A/A,B or anti-B hemolysis is limited to transfusions in progenitor cell transplant (PCT) recipients and newborns. In PCT recipients, transfusion support between myeloablation and engraftment may require washed or volume-reduced platelet components to avoid anti-A/A,B– or anti-B–associated hemolysis. Plasma in platelet concentrates may represent a significant percentage of a newborn's blood volume, placing newborns at higher risk than adults for ABO-related hemolysis. Some hospitals routinely wash or volume-reduce out-of-group platelet components for newborns.

Methods for Washing Platelet Components

Methods have been developed for manual and automated washing using blood cell processors.[75–77] Washed platelet components have a threefold increase in spontaneous activation, as well as impaired ADP-induced aggregation, compared with unwashed platelet components.[74] Washing platelets requires skill and experience to minimize platelet loss, activation, and clumping.[78] Automated cell processors are more likely to deliver a consistent result and are recommended. Kalman and Brown developed a protocol using the IBM 2991 Blood Cell Processor, which removed a mean of 99.6% of plasma proteins following a 1500-mL wash using 0.9% sodium chloride. That cell processor is currently marketed as the COBE 2991 Blood Cell Processor (COBE Laboratories, Lakewood, Colo.).

Washed platelet components should be used immediately after washing owing to lack of substrates to support platelet metabolism during storage. In vitro studies of new additive solutions for washing platelets suggest that a postwash storage duration of up to 48 hours may be feasible.[79]

VOLUME-REDUCED PLATELET COMPONENTS

Indications for Volume-Reduced Platelet Components

There are two indications for transfusing volume-reduced platelets: to prevent circulatory overload and to lessen the volume of any potentially adverse constituents in the plasma of platelet components. Volume-reduction can be achieved either during collection and processing of collections (primary volume reduction) or subsequently by recentrifugation of stored platelet components (secondary volume reduction).[79] Additional concentration of standard platelet components is controversial.

Hypervolemia

A typical argument to support the availability of such "super- or hyper-concentrated" platelet components for newborns is that a standard 50-mL unit of random donor platelet components represents more than half the blood volume of a 1-kg infant and may precipitate circulatory overload.[80] In vitro studies of recentrifuged, volume-reduced platelet components demonstrated satisfactory viability, and in vivo studies have demonstrated satisfactory survival of 51r-labeled concentrated platelets and post-transfusion platelet count increments.[81,82] Arguments against routinely reducing the volume of standard platelet components focus on the reliability of transfusing 5 to 10 mL/kg of standard platelet concentrates or apheresis platelets to increase the platelet count to $>100 \times 10^9$ L.[83] A secondary concern is that while satisfactory concentration of platelets may be achieved by experienced research technologists in a limited study, technologists working in routine transfusion service operations may not be able to achieve that level of quality control. A transfusion service undertaking recentrifugation of platelets must take special precautions to control for platelet loss, clumping, and dysfunction caused by additional handling.[78]

The AABB Pediatric Hemotherapy Committee published the results of a national survey of neonatal transfusion practices, noting that "because of the potential for harm, institutions transfusing volume-reduced platelets should monitor both the quality of the final product (i.e., the number of platelets, degree of clumping, and function) and in vivo effects such as post-transfusion increment in platelet count and adverse reactions, including altered vital signs and pulmonary distress."[84] The Committee made the observation that 61% of respondents reported a final desired volume of 10 to 15 mL, and an additional 30% desired 18 to 25 mL, both volumes being within the range likely to achieve the targeted platelet count increase using an unmodified platelet concentrate.

Recurrent Febrile Nonhemolytic Transfusion Reactions

In adults, the incidence of febrile nonhemolytic transfusion reactions (FNHTRs) is decreased when plasma-reduced platelet components are transfused.[85,86] This effect, similar to that of prestorage leukoreduction, is attributed to decreased leukocyte-derived proinflammatory cytokines, which accumulate in plasma of stored platelet components.[86,87] In children, a randomized, prospective, crossover study compared the frequency of acute reactions to post storage plasma-removed platelet components and to standard platelets.[88] Study platelet components were prepared by removing plasma from stored components and replacing it with an equal volume of ABO-compatible fresh frozen plasma (FFP). While there was a trend toward lower frequency of FNHTRs with post storage plasma removal, the results were not statistically significant.[88] The investigators could not explain why FNHTRs occurred less frequently in children than in adults. On the basis of these findings, the authors do not recommend removing plasma (with or without replacement using FFP) as a method to reduce the incidence of FNHTRs in children.

We believe that routine recentrifugation of platelet components is neither necessary nor prudent. As stated by the

Table 29–3 **Methods for Preparation of Secondary Volume-Reduced Platelet Components**

Method	Starting Platelet Component	*N*	Volume of Final Platelet Component (mL)	Platelet Count of Final Platelet Component ($\times 10^9$/mL)	In Vitro Platelet Function Studied after Volume Reduction	In Vivo Platelet Efficacy Studied after Volume Reduction

Modified from Schoenfeld H, Spies C, Jakob C. Volume-reduced platelet concentrates. Current Hematol Rep 2006;5:82–88.

AABB Committee on Pediatric Hemotherapy, " . . . volume reduction of platelet concentrates . . . should be reserved for special infants for whom marked reduction of all intravenous fluids is truly needed."[84]

Methods to Volume-Reduce Platelet Components

Primary Volume Reduction

Primary volume reduction of platelet concentrates occurs at the time of collection and processing of platelet components. Several studies have shown that platelet collections may be concentrated beyond current standards using new, high-efficiency apheresis collection devices with or without specialized platelet storage solutions.[89–93] Schoenfeld has evaluated and compared these experimental platelet components.[99] Since most hospital transfusion services do not have facilities to collect or adequately monitor the efficacy of such components, this discussion focuses on selective secondary volume reduction of standard platelet components.

Secondary Volume Reduction

Secondary volume reduction occurs after storage by recentrifugation to remove plasma and resuspend platelets in a decreased volume for immediate transfusion.[94] There is no standard method for preparing volume-reduced platelet concentrates. The functional characteristics of secondary volume-reduced platelet components prepared by different methods have been studied (Table 29–3).[80–81,95–99] If secondary volume reduction of platelet components is necessary, the authors recommend the method of Moroff and colleagues.[80] This method uses standard platelet concentrates that may be stored for as long as 5 days before recentrifugation, a standard blood bank refrigerated centrifuge, and manual resuspension of the centrifuged platelets.

Methods for collecting platelets by apheresis and storing them in platelet additive solutions in a reduced volume of plasma have also been developed. Proponents report that decreased plasma reduces allergic and febrile transfusion reactions, facilitates ABO-incompatible platelet transfusions, and is the preferred approach for some pathogen-inactivation methods.[100–103]

Chapter 30

Blood Management: Conservation, Salvage, and Alternatives to Allogeneic Transfusion

Beth Shaz

INTRODUCTION

Blood management is the term given to the practice of minimizing allogeneic blood use while maximizing patient outcome. The four main tenets of blood management are (1) to focus on guideline-driven proper use of banked blood and minimizing its inappropriate use, (2) to utilize pharmaceutical preparations that prevent, minimize, or control blood loss, usually in the operative setting, (3) to employ blood conservation methods, and (4) to have a multidisciplinary approach. Blood conservation includes preoperative (preoperative autologous donation), intraoperative (hemodilution and blood salvage), and postoperative (blood salvage) techniques. A multidisciplinary approach makes use of the entire team of health care providers in the uniform goal of minimizing transfusion in the treatment of patients. This approach incorporates addressing preoperative anemia, using meticulous anesthetic and surgical techniques intraoperatively, and avoiding overphlebotomy postoperatively. This chapter focuses on these four topics.

GUIDELINE-DRIVEN BLOOD PRODUCT USE

Although the blood supply in developed countries has become increasingly safe, mortality and morbidity continue to be associated with transfusions. The risks of transfusion are detailed in subsequent chapters. The risk of transfusion must be weighed against the benefit. A retrospective review of patients who declined blood transfusion showed an increase in morbidity and mortality in proportion to decreasing hemoglobin at a hemoglobin level below 8 g/dL.[1] Therefore, for each patient, depending on co-morbidities, a transfusion threshold should exist. Creating restrictive transfusion criteria reduces the likelihood of transfusion with an average savings of a single unit per transfused patient.[2] Prior to creation of the guidelines, perform an audit to understand the established transfusion practice. Transfusion guidelines should be created by a multidisciplinary team based on evidence in the literature (an example is shown in Fig. 30–1). Prior to implementation of the guidelines, education is required to ensure the guidelines are understood and followed. After implementing the guidelines, perform a repeat audit to guarantee they are being followed. This practice can also identify areas that need continued improvement.[3,4]

PHARMACEUTICAL PREPARATIONS THAT DECREASE BLOOD LOSS

Desmopressin

Desmopressin (DDAVP; 1-deamino-8-D-arginine-vasopressin) is a vasopressin analog that increases the circulating levels of factor VIII and von Willebrand factor in patients with hemophilia A and von Willebrand disease, respectively.[5] Side effects of DDAVP include hypotension, hyponatremia, headache, and decreased urine output.[6] The Cochrane collaboration reviewed 25 clinical trials of DDAVP use in adult elective surgery without underlying bleeding disorders and concluded that DDAVP does not reduce blood loss, risk of allogeneic transfusion, volume of red blood cells (RBCs) transfused, or mortality. The majority of the studies were performed in cardiac surgery patients.[7]

Antifibrinolytics

Aprotinin

Aprotinin, a proteinase inhibitor obtained from bovine lung, inhibits multiple mediators of inflammatory responses, fibrinolysis, and thrombin generation.[6] Aprotinin inhibits kallikrein at higher doses and plasmin at lower doses (Fig. 30–2). Anaphylactic reactions are possible, especially when patients are reexposed to aprotinin; therefore, a test dose is required.[6] In the Cochrane database of systematic reviews, aprotinin reduces the need for allogeneic blood transfusion, bleeding, and the need for reexploration in cardiac bypass surgery patients.[8] Considerations in the use of aprotinin include the following: use of half versus full dose, use in surgeries other than bypass, use of aprotinin versus lysine analogs, and cost.

Aprotinin has been administered in several dose sizes: the kallikrein-inhibiting full dose ("full Hammersmith"), the plasmin-inhibiting half-dose, and a pump-prime-only dose.[8] All three doses decrease blood transfusion, both in the number of products received and the percentage of patients transfused. This also held true when patients were stratified for risk of bleeding. There is a concern of an increased risk of myocardial infarction with the pump-prime-only dose.[9] A study of the cost effectiveness of the high and low doses in coronary artery bypass patients found that in primary CABG patients aprotinin was cost neutral, whereas in repeat CABG patients both doses resulted in cost savings over placebo ($4483 for the low dose and $6044 for the high dose; 2005 USD).[10]

Southern General Hospital

GUIDELINES FOR BLOOD TRANSFUSION

This guideline promotes best practice regarding blood use within the Southern General Hospital. Recent audit revealed widespread differences in practice and confusion as to when and how to prescribe blood.

INDICATIONS FOR TRANSFUSION

1. Acute Blood Loss

An acute blood loss of greater than 20% of blood volume (about 1000 mls blood) will often need a transfusion. Do not delay ordering blood in situations where blood loss is acute and rapid. If blood loss is very rapid, the hospital Major Haemorrhage Protocol should be activated by dialing 3333.

2. For Surgical Patients

Consider transfusion if:

- Pre-operative haemoglobin is less than 80 g/l and the surgery is associated with the probability of major blood loss.
- Post-operative haemoglobin falls below 70 g/l.
- Pre-operative anaemia MUST be investigated, as medical management may be more appropriate than transfusion.

3. Anaemia in Active Myocardial Infarction (Hb below 100g/l)

These patients are among the few who may benefit feom a Hb above 80. Transfusion to an Hb of 100 g/l is acceptable but to overshoot to 110 may be excessive. Evaluate effect of each unit as it is given.

4. Anaemia in Other Patients (Hb below 100 g/l but above 70 g/l)

Consider transfusion in normovolaemic patients ONLY if they have symptomatic anaemia. Symptoms and signs of anaemia include:

- Shortness of breath for no other reason
- Angina
- Syncope/postural hypotension
- ST depression on ECG
- Tachycardia for no other reason

Transfusion above 100 g/l is very rarely indicated and WILL be questioned by haematology staff.

- Think before transfusion. Blood is expensive and potentially dangerous if used inappropriately.
- Reassess after each unit given. Do you need to give more?
- Stop if symptoms/signs shown above resolve.
- Stop if you have reached an adequate Hb i.e. above 80 g/l in symptomless patients (100 g/l in acute MI).

Figure 30–1 Example of guidelines for red cell transfusion. (From Garrioch M, Sandbach J, Pirie E, Morrison A, Todd A, Green R. Reducing red cell transfusion by audit, education and a new guideline in a large teaching hospital. Transfus Med 2004;14:27.)

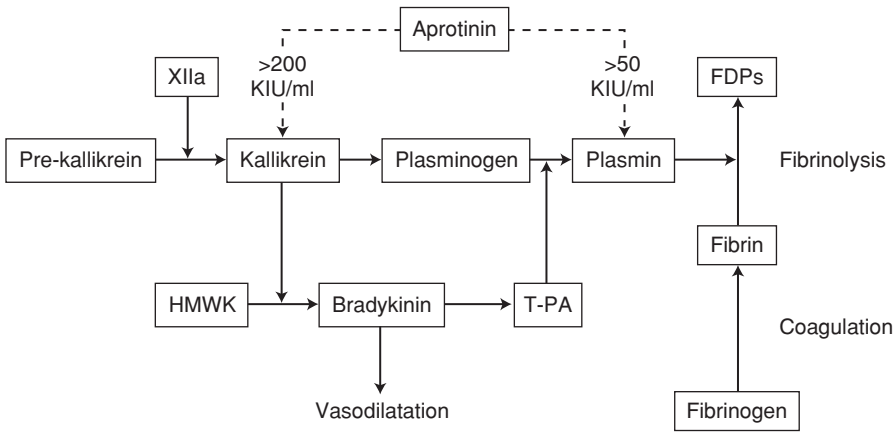

Figure 30–2 Aprotinin inhibition. (From Porte RJ, Hendriks HG, Slooff MJ. Blood conservation in liver transplantation: The role of aprotinin. J Cardiothorac Vasc Anesth 2004;18(4 Suppl):31S–37S.)

Aprotinin has been used in other surgeries including orthopedic surgery, liver transplantation, liver resection, and vascular surgery.[8] In liver transplantation, studies have demonstrated a decrease in transfusion with no difference in mortality.[11,12] In major orthopedic surgery, there are conflicting data about the usefulness of aprotinin, and the studies consist of small numbers of patients with varying procedures.[13–15] Small trials have shown decreased transfusion rates with aprotinin versus placebo in orthognathic surgery[16] and major thoracic surgery.[17,18] In summary, aprotinin has not been extensively studied in noncardiac surgery but may be beneficial if substantial blood loss is predicted.

e-Aminocaproic Acid (EACA) and Tranexamic Acid (TXA)

TXA and EACA are synthetic lysine analogs that inhibit fibrinolysis. These drugs block the lysine-binding site on the plasminogen molecule, which inhibits the formation of plasmin and therefore inhibits fibrinolysis. In the Cochrane database of systematic reviews, TXA, but not EACA, statistically significantly reduces the rate of allogeneic transfusion.[8]

There are only a handful of trials with small numbers of patients using EACA to decrease the rate of transfusion, and a few more trials using TXA. A small study demonstrated a small but statically significant decrease in transfusion rate in scoliosis repair in EACA versus placebo.[19] A similar study with TXA showed decreased blood loss, with no difference in transfusion.[20] The use of TXA versus placebo reduced the total number of packed red cell units transfused in patients receiving coronary artery bypass grafting on and off pump.[21] No difference in transfusion rates in total knee replacement was seen with the use of TXA or aprotinin.[22,23] Multiple small trials with either TXA or EACA for a variety of surgeries have demonstrated conflicting data on their ability to decrease allogeneic red cell transfusion, but in general more benefit has been seen in procedures associated with greater blood loss.

Comparison of Antifibrinolytics

Antifibrinolytics decrease the need for allogeneic transfusion. Aprotinin is the most expensive but the most frequently studied of the antifibrinolytics. The Ischemia Research and Education Foundation recently published an observational study involving 4374 patients undergoing cardiac revascularization. They compared aprotinin, aminocaproic acid, and tranexamic acid with no agent and discovered that aprotinin was associated with serious end-organ damage involving the heart, brain, and kidney. There was a dose-response relationship for aprotinin with increased death, renal dysfunction, and cardiovascular events at a higher dose. All three antifibrinolytics reduced blood loss equally, but aminocaproic acid and tranexamic acid were not associated with serious end-organ damage.[24] In a recent study in cardiac surgery patients of aprotinin versus tranexamic acid versus control, aprotinin significantly decreased the likelihood of allogeneic transfusion.[25] A similar study in coronary artery bypass patients receiving aspirin showed no significant difference between aprotinin, TXA, and EACA on blood loss or transfusion.[26] In the Cochrane review, no clinical significant difference between TXA and aprotinin on transfusion could be found, but there is significant heterogeneity in the trials.[8] In orthotopic liver transplantation, use of TXA versus aprotinin showed no difference in transfusion or mortality.[27]

Most of the data on antifibrinolytics is in cardiac surgery patients. There is a debate about its use in primary surgeries, where blood loss should not be substantial and the drug may therefore be of limited benefit. The second most common use in the literature is in orthopedic surgery, where it can be beneficial in surgeries with substantial blood loss. Few trials in orthotopic liver transplantation have shown a decrease in transfusion, but there are multiple case reports of thrombotic complications with its use.[28]

Recombinant Factor VIIa (rFVIIa)

Factor VIIa binds to tissue factor to activate factors IX and X, thereby activating factor V, which converts prothrombin to thrombin. Thrombin activates platelets and factors VII, V, and XI. This creates a thrombin burst, which converts fibrinogen to fibrin for clot formation (Fig. 30–3).[29] Recombinant activated factor VII (rFVIIa) is licensed for use to control bleeding in hemophilia with inhibitors, but there are case series demonstrating its success in controlling severe or refractory bleeding in nonhemophilic patients as well. One randomized controlled study in patients undergoing retropubic prostatectomy demonstrated a reduction in blood loss, number of units transfused, and likelihood of transfusion.[30] rFVIIa did not reduce blood loss or transfusion in trauma patients undergoing pelvic reconstruction.[31] A third trial of rFVIIa versus placebo in patients receiving liver resection demonstrated no change in transfusion or blood loss.[32] In a recent trial of its use in intracranial hemorrhage, there was an increased rate of thrombosis, especially as the dose was escalated.[33] rFVIIa may decrease blood loss and decrease transfusion needs in cases of large blood loss but carries a risk of thrombosis and a high cost.

Fibrin Sealant

Fibrin sealant is the combination of thrombin and fibrinogen mixed with calcium to form fibrin, which is used as a topical hemostatic agent. Products may contain antifibrinolytics (aprotinin) to reduce fibrinolysis or factor XIII to increase strength of the clot (Fig. 30–4).[34] A variety of commercially and individually produced fibrin sealants are available. Bovine thrombin products are commonly used but have a risk for allergic reactions and antibody formation. Antibodies to bovine thrombin cross-react with human factor V, leading to factor V deficiency and risk for hemorrhage.[35] In contrast, human thrombin, though virally inactivated, has a small risk for transfusion-transmitted disease. Currently, two fibrin sealant products consisting of human fibrinogen, human thrombin, calcium chloride, and aprotinin (bovine) are commercially available in the United States. Alternatively, automated devices exist to produce fibrin sealant from autologous plasma.[36] Another option is autologous fibrin glue prepared from the cryoprecipitated portion of autologous plasma; after thawing, this material is mixed with bovine thrombin immediately before application to the surgical field. A disadvantage of fibrin sealant is the time it takes to prepare, especially autologous products, and also the time for the clot to form.[34] Fibrin sealants have been studied in a number of surgeries, including prostatectomy, lung resection, liver resection, carotid endarterectomy, cardiac surgery, and orthopedic surgery.[34] In the Cochrane database of systematic reviews, fibrin sealants reduced allogeneic transfusion and decreased intraoperative and postoperative blood loss, but most trials were small and unblinded, resulting in less reliable data.[37]

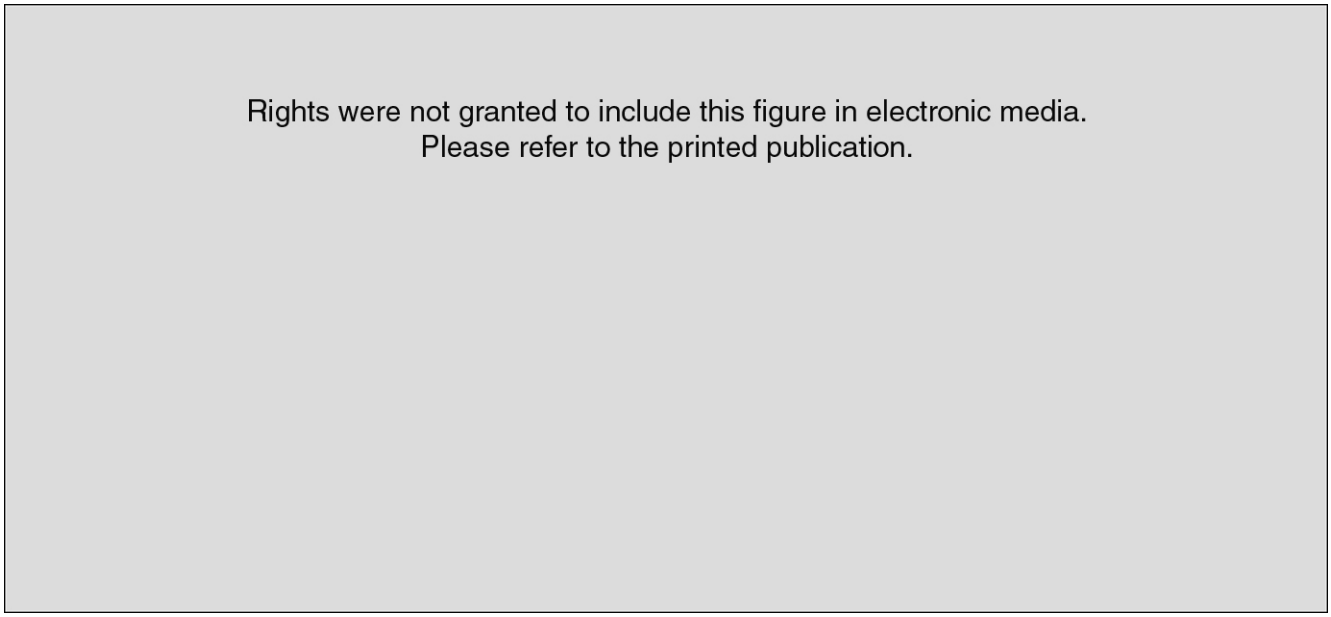

Figure 30–3 Role of FVIIa in coagulation. **A,** Coagulation is initiated when coagulation proteins and platelets come into contact with the extravasculature. Factor VII binds to tissue factor, is activated, and activates both factor IX and factor X. The factor Xa forms a complex with factor Va on the tissue factor–bearing cell and activates a small amount of thrombin. This thrombin acts to amplify the initial coagulation signal by activating platelets, causing release of factor V, activating factor V, cleaving factor VIII and releasing it from vWF, and activating factor XI. In the propagation phase, factor IXa, formed by factor VIIa/tissue factor or generated on the platelet surface by factor XIa, forms a complex with factor VIIIa to activate factor X on the platelet surface, where, in complex with factor Va and in the presence of prothrombin, it is protected from inhibition. Formation of the factor Xa/Va complex results in a burst of thrombin generation. **B,** In hemophilia, the initiation and amplification phases proceed normally. The propagation phase is absent or significantly decreased because factor Xa cannot be generated on the platelet surface. High-dose factor VIIa acts to partially restore platelet surface factor Xa generation so that factor Xa/Va complex formation proceeds and the propagation phase is improved relative to the hemophilic state. (From Roberts HR, Monroe DM, White GC. The use of recombinant factor VIIa in the treatment of bleeding disorders. Blood 2004;104:3858–3864.)

BLOOD CONSERVATION

Autologous Blood

Autologous blood can be collected from a patient in advance of anticipated blood loss (preoperative donation) or at the start of the procedure (acute normovolemic hemodilution); in addition, shed blood can be salvaged for reinfusion both during surgery and in the postoperative period (Table 30–1). As early as the late 19th century, the concept of using a patient's own blood as a source of transfusable RBCs was born of necessity because allogeneic transfusions were fraught with immunologic risks. Early authors proposed the recovery of blood shed during childbirth, ectopic pregnancy, and splenectomy.[38,39] With the discovery of the ABO blood group system, the development of approaches for storage of blood and preparation of components, and the need during two world wars for a large and immediately available blood supply, interest in autologous blood waned. The appearance in the early 1980s of the human immunodeficiency virus (HIV) as a transfusion-transmissible complication of allogeneic transfusion fostered a recurrence of interest in autologous blood techniques. As the risk of transfusion decreased and understanding of the risks and costs of autologous donation increased, there has been a decline in the utilization of preoperative blood donation.[40] Blood collection statistics bear out this trend: donations of blood for autologous use increased from 28,000 units in 1982 to a peak of 1,117,000 units in 1992 and have currently decreased to 651,000 units in 1999 (Fig. 30–5).[41–44]

Preoperative Erythropoietin

Erythropoietin is a 165-amino-acid glycoprotein hormone, which is synthesized in fetal liver and adult kidney as a response to hypoxia to stimulate erythropoiesis. Erythropoietin receptors have been identified on both hematopoietic and other (brain, heart, liver, and retina, vascular endothelium, gastrointestinal tract, and reproductive tract) tissues. Therefore, erythropoietin likely mediates additional activities, such as having a protective antiapoptotic effect.[45] Erythropoietin corrects anemia caused by renal failure, cancer, cancer therapy, and HIV.[46] Erythropoietin is contraindicated in patients with uncontrolled hypertension. Adverse events associated with its use include thrombotic events, hypertension, seizures, and rare cases of pure red cell aplasia.[6] Erythropoietin can be used preoperatively, with or without preoperative blood donation, or with acute normovolemic hemodilution in elective surgery.[46] Two to four weeks is necessary for adequate erythropoietin-stimulated erythropoiesis to occur.[46] Depending on the estimated blood loss, patient's blood volume, and amount of time prior to surgery, erythropoietin may be useful.

Because erythropoietin increases the preoperative hemoglobin, it can be used in mildly anemic patients preoperatively to decrease the risk of transfusion in elective surgeries with moderate blood loss.[47] Erythropoietin given perioperatively decreases the number of intraoperative and postoperative transfusions and results in improved 1-year survival rate.[48] One study demonstrated that patients receiving daily erythropoietin (300 IU/kg or 100 IU/kg subcutaneously beginning 10 days prior to orthopedic surgery for a total of

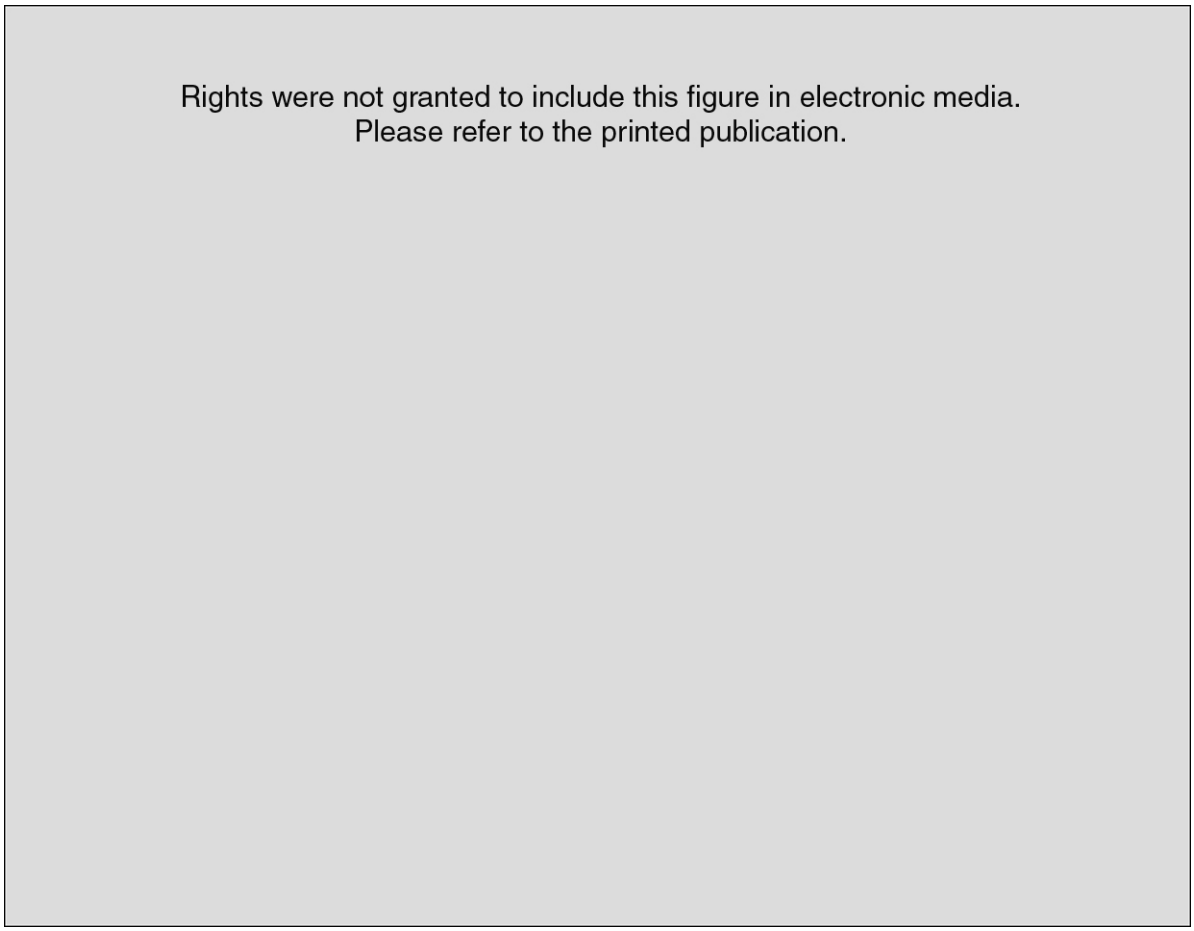

Figure 30–4 Schematic drawing of the coagulation cascade and composition of components of the fibrin tissue adhesive (FTA). (From Levy O, Martinowitz U, Oran A, Tauber C, Horoszowski H. The use of fibrin tissue adhesive to reduce blood loss and the need for blood transfusion after total knee arthroplasty. A prospective, randomized, multicenter study. J Bone Joint Surg Am 1999;81:1580–1588.)

15 doses) versus placebo perioperatively had significantly decreased transfusion rates. This improvement was significant even in patients with a preoperative hemoglobin level above 13 g/dL.[49] An earlier study with erythropoietin given daily perioperatively to patients undergoing elective hip replacement showed a decreased transfusion rate with erythropoietin compared with placebo, but the patients who benefited most had a hemoglobin below 13.5 g/dL at baseline.[50] Preoperative erythropoietin has also been shown to decrease allogeneic transfusion in anemic patients receiving elective open heart surgery or gastrointestinal cancer resection.[51] In anemic patients who are not eligible to donate autologous blood preoperatively, erythropoietin decreases the likelihood of allogeneic blood transfusion.

Iron supplementation maximizes the benefit of erythropoietin used either orally or intravenously.[52] Other major

causes of hyporesponsiveness to erythropoietin include folic acid, vitamin B_{12}, vitamin C deficiency, infection, inflammatory states, and chronic blood loss.[53]

Erythropoietin has also been used in combination with preoperative autologous blood donation to increase the number of units donated or with other blood conservation strategies, as discussed in the sections on Indications for Autologous Whole Blood Collection in Combination with Erythropoietin and Acute Normovolemic Hemodilation in Combination with Erythropoietin.

Preoperative Iron Supplementation

Correcting iron deficiency anemia prior to surgery should decrease the likelihood of the need for allogeneic transfusion.[54] Iron therapy is not beneficial in non–iron-deficient patients without concomitant erythropoietin.[52] A preliminary study shows a decrease in allogeneic blood transfusion with an accompanied reduction in morbidity-mortality rate and length of hospital stay with the use of intravenous iron preoperatively in patients undergoing displaced subcapital hip fracture repair.[55]

Advantages and Disadvantages of Autologous Blood Transfusion

Advantages

In the past, autologous donations have been viewed as a strategy for obtaining blood to augment short allogeneic supplies. More relevant in current times is the use of autologous blood to eliminate the risk of transfusion-transmitted microorganisms, in particular HIV and hepatitis viruses. The institution of increasingly sensitive tests for such infections, including nucleic acid testing, has softened the impact of this argument; however, the risk of future incursions into the blood supply by new infectious agents remains a threat. Immunologic complications, such as antibody-mediated hemolysis and leukocyte-associated febrile reactions, are eliminated with the use of autologous blood. Supported by human and animal data, some authors also believe that allogeneic transfusions induce immunosuppression in the recipient and that autologous blood may not.[56] Only prospective observational studies have been performed to answer the question of allogeneic versus autologous blood transfusion and the risk of postoperative infection.[57–59] Other advantages include the stimulation of erythropoiesis in the repeatedly bled autologous donor, which could speed recovery from postoperative anemia.[60] Intraoperatively salvaged RBCs are typically transfused back to the patient within a few hours after collection, thereby precluding the acquired membrane defects and enzyme deficiencies (2,3-diphosphoglycerate and adenosine triphosphate) that develop during refrigeration (the "storage lesion").[61]

Disadvantages

Autologous techniques are not without drawbacks. Although an ideal preoperative donation schedule should allow sufficient time for compensatory erythropoiesis to occur, some individuals develop donation-induced anemia at the time of admission for surgery. Concerns regarding complications of donation in patients with underlying cardiac disease have been raised[62] although it can be difficult in such settings to distinguish between an untoward effect of blood letting and the natural history of the baseline condition. Clerical errors, including release of the wrong unit of blood, still occur.[63] Finally, although it is rare, autologous blood may itself pose infectious risks. *Yersinia enterocolitica*, a common cause of community-acquired diarrhea, persists in the bloodstream for many weeks after infection and can grow at refrigerator temperatures; an individual who donates blood during this time period can be made severely ill by later transfusion of the component.[64]

Costs of Autologous Blood Techniques

As the allogeneic blood supply has become safer, more attention has been focused on the costs associated with autologous transfusion techniques. Costs come from unused autologous collections (e.g., when a patient has donated enough blood to match the mean number of components used by others undergoing the procedure but requires less). This problem is magnified by overcollection and unnecessary utilization (e.g., in plastic surgery) and by the extra work involved in deviation from routine, large-scale allogeneic collection practices.[65] In one hypothetical cost-utility analysis of patients undergoing primary elective hip replacement, the cost effectiveness of autologous transfusion per quality-adjusted life-year (QALY) was estimated at an extremely high 3.4 million. However, if allogeneic transfusions were assumed to increase the risk of postoperative bacterial infection, a possibility suggested by some workers,[66–68] the cost of using autologous blood fell to less than $50,000 per QALY, and the procedure became dominant (cheaper to use than allogeneic blood) as the infection risk rose.[69] Some authors have suggested that autologous blood could be kept cost effective by streamlining collection and processing, including forgoing infectious disease testing of autologous donors.[70,71] Reducing costs through the intentional use of autologous blood by a recipient other than the donor ("crossover") is not recommended. Only 30% of collections are typically eligible for allogeneic use, and the costs, complexity, and risk of error of the transition all serve to negate the value.[72]

Preoperative Autologous Donation

Indications for Autologous Whole Blood Collection

The decision to use preoperative autologous blood donations should be predicated on the type of surgery, the amount of time available for donation and hematopoietic reconstitution, the patient's hematocrit, and the predicted vigor of the erythropoietic response to donation. Patients planning to undergo elective orthopedic surgery are ideal candidates for autologous transfusion, because they require moderate amounts of blood during and immediately after surgery, and they typically have sufficient time prior to surgery to make multiple donations.[73–75] Open heart surgery and vascular surgery are other procedures in which autologous blood collections have led to reduction or elimination of allogeneic blood use.[6] The use of preoperative autologous blood donation has also been reported for a variety of other surgical procedures, including radical prostatectomies, hysterectomies, and other gynecologic procedures, gastrointestinal surgery, and neurosurgery.[76,77] Donors of bone marrow for transplantation undergo multiple iliac crest aspirations and may develop a moderate anemia; advance donation of autologous blood forestalls the need for allogeneic transfusions.[78] As surgical techniques change, the need for blood transfusions may be affected, and in such instances the role of autologous blood should be reexamined. Radical prostatectomy is a case in point: ten years ago many hospitals encouraged patients undergoing the procedure to donate autologous blood,[79,80] but today in some hands fewer than 2% of patients require blood, and autologous blood donations may be superfluous.[81,82] Blood transfusion is also rarely necessary in plastic surgical procedures, and the collection of autologous blood in such cases is often frivolous.[83]

Autologous blood can be collected from a pregnant woman for use during childbirth. The expanded maternal blood volume contributes a substantial safety cushion, and the donation process appears safe for both mother and fetus.[84] However, the use of blood transfusions in uncomplicated pregnancies is low (1%) even in patients undergoing cesarean section (3.3%).[85–87] A role for autologous collections may exist for patients with placenta previa, in which the likelihood of transfusion may exceed 25%, and the condition is often identified with sufficient time for advance blood donations.[88] In addition, autologous blood has been collected from patients with unusual antibodies discovered during the pregnancy.[89]

Long-term frozen storage of autologous RBCs in the absence of an anticipated transfusion episode is both ineffective and expensive. An exception is the storage of blood by individuals with high-frequency or complex alloantibodies, for whom stockpiling of rare autologous units may be beneficial. Even here, however, the likelihood that such blood would be helpful is slim. To be of value, sufficient autologous blood would have to be available to meet the needs of an unexpected emergency; furthermore, delays in sending the blood expeditiously to the hospital where it is needed and in preparing units (thawed and washed free of the glycerol cryoprotectant) would make its use unwieldy.

Indications for Autologous Whole Blood Collection in Combination with Erythropoietin

Preoperative erythropoietin and preoperative autologous donation have the equivalent likelihood of allogeneic red cell transfusion.[90–92] The superiority of adding erythropoietin to preoperative autologous donation was demonstrated in a three-arm study of preoperative erythropoietin alone, erythropoietin plus preoperative autologous donation, versus preoperative autologous donation alone in patients undergoing total joint arthroplasty with an initial hemoglobin of ≤14.0 g/dL. Allogeneic transfusion rates were lowest in patients who had received erythropoietin and predonated autologous blood (11% vs 28% or 33%).[93]

When large blood loss is expected and multiple units of autologous blood are needed, erythropoietin increases the number of preoperative autologous blood units that can be donated.[47] In one study, orthopedic patients with a baseline hematocrit of ≤39% were requested to donate six weekly autologous units. Erythropoietin (six weekly doses) versus placebo significantly increased the number of units donated (4.5 vs 3.0), resulting in fewer patients who received erythropoietin being transfused allogeneic blood (26% vs 38%).[94] An earlier small study in women undergoing total hip replacement with hematocrit <40% showed donation of more units with erythropoietin versus placebo (4.1 vs 2.8 units) resulted in less transfused allogeneic blood (0.4 vs 1.2 units). This study had an aggressive donation schedule, with one donation every 3 to 4 days for 3 weeks, and a high transfusion rate of 4 units on average.[95] A similar study in spine surgery showed benefit in erythropoietin with autologous donation, evidenced by a decrease in allogeneic blood and hospital stay.[96] A single small study in patients with iron deficiency anemia (hematocrit ≤ 33%) and gastrointestinal cancer showed an increase in autologous unit donation and a trend toward decrease of allogeneic blood transfusion with the use of intravenous iron and erythropoietin preoperatively versus intravenous iron alone.[97] A small study in patients undergoing coronary artery bypass surgery demonstrated that erythropoietin increased the number of autologous units collected and decreased the rate of allogeneic blood transfusion.[98]

Other studies have demonstrated an increase in autologous units donated preoperatively with the use of erythropoietin but no significant decrease in allogeneic blood transfusion. In patients undergoing hysterectomy, erythropoietin increased the number patients able to donate 3 units in 2 weeks but did not decrease the transfusion of allogeneic blood.[99] Patients undergoing resection of rectal cancer were able to donate more red cells (4 units in 2 weeks) if treated with erythropoietin, but there was no difference in autologous or allogeneic transfusions.[100] Multiple studies show no use for erythropoietin in combination with preoperative autologous donation in nonanemic patients undergoing surgery, even with large blood needs.[101–103]

Clearly determining which patients are most likely to benefit from erythropoietin with or without preoperative autologous donation depends on the estimated blood loss for a surgical procedure, the patient's ability to donate autologous blood, the amount of time available prior to surgery, the baseline hematocrit, and the patient's blood volume. A single institution's experience with a tailored program of no preoperative autologous donation in patients with hematocrits greater than 39%, autologous blood donation (2 weekly donations) in patients with hematocrits between 37% and 39%, and erythropoietin if the hematocrit was less than 37% (3 weekly doses preoperatively) showed a decrease in transfusion (88% vs 57%), especially in patients with hematocrits greater than 39%, (majority of the patients).[104] This study proved the concept of tailoring preoperative treatment based on a patient's baseline hematocrit.

Indications for Other Autologous Components

Although autologous plasma is easily prepared from whole blood, little need exists for plasma in most elective surgery.[105] Autologous platelet-rich plasma can be prepared at the start of open heart surgery, using apheresis equipment before bypass, to be returned to the patient after heparin reversal.[106] Because thrombocytopenia or an acquired platelet defect can occur after blood passes through the membrane oxygenator,[107] the theoretical advantages of transfusing platelet-rich plasma should include improvement in hemostasis and reduced transfusion requirements. Although initial studies of this approach provided supportive data,[106,108–110] later prospective, blinded protocols were not able to demonstrate a reduction in blood use in either primary heart surgery or reoperations.[111,112] In addition, the harvesting of platelet-rich plasma has been followed by intraoperative heparin resistance, possibly owing to release of platelet factor 4 and other procoagulants from platelets damaged during the collection.[113] The Cochrane Database of systematic reviews identified 19 trials of platelet-rich plasmapheresis in mostly cardiac surgery patients for which allogeneic transfusion data were available. They concluded that platelet-rich plasmapheresis reduces allogeneic transfusion, but there was heterogeneity in the studies and the majority was unblinded; therefore, the procedure is not justified at this time.[114]

Collecting Autologous Blood

Autologous blood donations are well tolerated by a variety of ostensibly high-risk donors, including the elderly,[76,115] children,[116] pregnant women,[117,118] and patients with atherosclerotic coronary artery disease.[119] One group reported an increased frequency of serious reactions among autologous donors at blood collection facilities, although this may reflect an intentionally conservative approach to patients (compared with the "normal" volunteers to which donor centers are accustomed).[120] A weekly phlebotomy schedule fosters some degree of RBC regeneration before surgery (in one study, a mean of 522 mL of RBCs donated over 3 weeks resulted in a mean RBC production of 351 mL).[121] However, the most important medical problem associated with autologous donation is anemia developing during the collection interval. When this occurs, it is typically as a result of marginal iron stores and insufficient erythropoietic response (with little or no increase in serum erythropoietin levels), probably because the hematocrit of most donors is not allowed to fall below 30%.[122] This situation may be improved by the administration of recombinant human erythropoietin.[123] Many variables affect the response of blood donors to this drug, including route of administration, adequacy of iron stores, and method of iron supplementation (oral vs parenteral).[124,125] Especially in the United States, the expense of recombinant human erythropoietin has limited its use to situations in which autologous blood donation might otherwise be difficult or impossible (e.g., in a patient who is already anemic).[94,95] An alternative approach employs RBC apheresis—collection of two units of RBCs (without plasma)—because each collection enhances the rate of compensatory erythropoiesis.[126] Other advantages of RBC apheresis include increased time between donation and surgery, which allows more time for compensation for the red cell loss, and savings in time and cost.[127]

Provided that the donor has satisfactory iron stores and that bone marrow erythropoiesis can occur in a timely fashion, blood may be comfortably collected from an autologous donor on a weekly schedule. Oral ferrous sulfate is commonly prescribed (325 mg three times daily) although the amount absorbed may not be sufficient to counter the iron lost with the donations.[128,129] In non–iron-deficient patients undergoing preoperative autologous blood donation, oral or intravenous iron versus no iron did not increase the number of units donated or decrease the need for allogeneic transfusion.[130] The shelf life of refrigerated whole blood is limited to 42 days with current formulations of anticoagulant-preservative solutions, and a schedule for multiple donations is usually fits into this 6-week window. Alternatively, some or all of the units can be frozen at −65°C, with glycerol as a cryopreservative, for up to 10 years. Although frozen units allow collections to occur over a longer period, the flexibility of utility at the time of surgery is affected: thawing and deglycerolizing takes a few hours, and the thawed units have an outdate of 24 hours.

Intraoperative Autologous Transfusion: Blood Salvage

Several techniques have been developed for the salvage and reinfusion of blood lost during an operative procedure. Interest in intraoperative salvage has been spurred by the introduction of pumps, separation chambers for washing RBCs, and increasing automation of the collection process.[131,132] The simplest approach—direct reinfusion without washing—involves collection of blood under low vacuum pressure in a plastic bag seated within a hard outer canister. An anticoagulant, usually citrate, is added. As soon as the bag is full, or within 4 hours after the start of the collection (to prevent bacterial growth), the contents of the bag are reinfused through a standard blood filter to the patient (Fig. 30–6). RBCs shed into a surgical field, already poten-

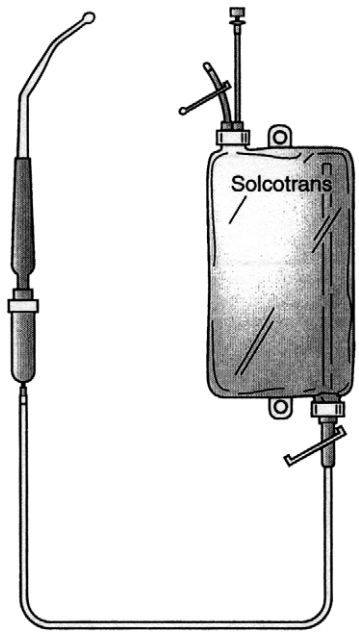

Figure 30–6 Equipment for direct reinfusion of perioperatively salvaged blood without washing. A 600-mL plastic bag is seated within the rigid plastic outer shell. A suction aspirator wand and filter are connected to the bottom port; vacuum suction is connected to the top left port. The top right port is connected to a blood filter for transfusion to the autologous recipient. (From Solco Basle, Rockland, Mass., and Williams & Wilkins, with permission.)

tially damaged by their travail, are accompanied by activated coagulation factors and platelets, cellular debris and soluble factors released from injured tissue cells, pharmaceuticals applied to the field, and irrigant solutions. Despite this scenario, salvaged blood has been reinfused directly into patients with few untoward consequences.

Alternatively, the contents of the bag can be washed with saline. Devices that include a reservoir for collecting the salvaged blood and a centrifuge for washing are available (Fig. 30–7) to collect and process large volumes (e.g., 225 mL of RBCs with a final hematocrit of 50% in less than 3 minutes).[133] With these techniques, intraoperative blood salvage has become practical in situations in which blood loss may be extremely rapid, such as trauma or liver transplantation. Approximately half of the blood lost during a surgical procedure can be recovered; the rest is irretrievably absorbed by drapes and sponges or damaged during collection.[134]

Complications of intraoperative salvage are surprisingly infrequent. The hematocrit of salvaged unprocessed blood is typically low because of a combination of dilution from irrigation fluids and some degree of mechanical hemolysis.[135] Free hemoglobin levels may exceed 1000 mg/dL, and in the recipient this can result in hemoglobinemia and hemoglobinuria (Table 30–2). Nevertheless, renal sequelae are uncommon.[136] The survival of chromium 51–labeled salvaged cells is normal in most patients, presumably because damaged cells are cleared during processing.[137,138]

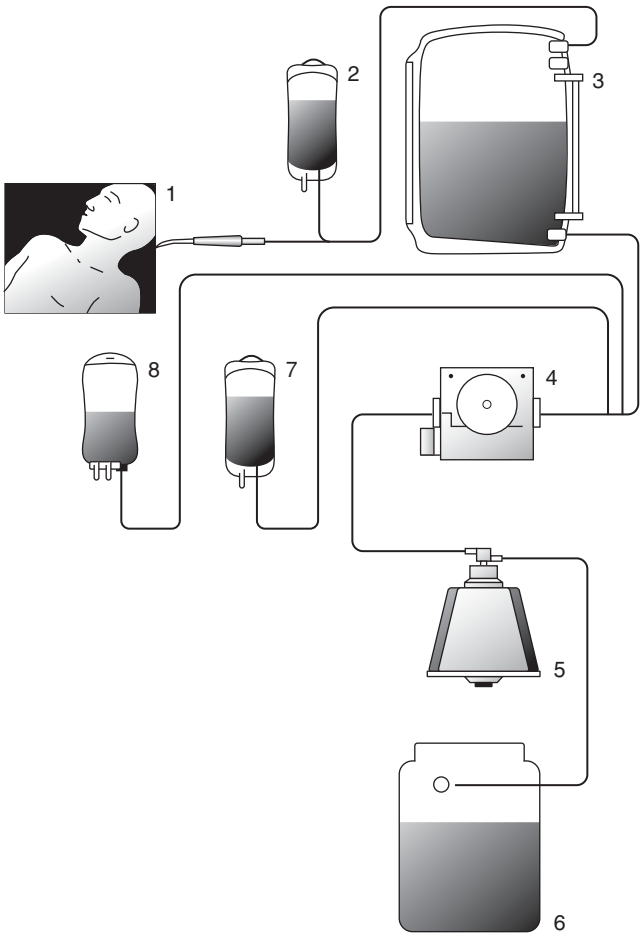

Figure 30–7 Schematic of an instrument used for collection and washing of perioperatively salvaged blood. Shed blood is suctioned from the operative field (1), an anticoagulant is added (2), and the blood moves past a mesh filter into a reservoir (3). A pump (4) forces the blood into a spinning plastic centrifuge bowl (5). With separation, plasma flows into a waste bag (6); saline (7) is continuously pumped into the bowl to wash the packed red blood cells. At the completion of washing, the red blood cells are moved into a reinfusion bag (8) for return to the patient. (From Haemonetics, Braintree, Mass., and Williams & Wilkins, with permission.)

Coagulation abnormalities are often observed in recipients of large volumes of salvaged blood and include hypofibrinogenemia, elevated fibrin degradation products, thrombocytopenia, and prolonged prothrombin and partial thromboplastin times.[139,140] In general, this clinical picture is related to a combination of the characteristics of the salvaged blood and hemodilution in the recipient. After exposure to serosal surfaces in the operative field, blood becomes depleted of coagulation factors and platelets; in the case of unwashed autologous blood, fibrin degradation products accumulate.[141] Although the clinical picture can resemble that of disseminated intravascular coagulation, which in theory might be initiated by phospholipids and other materials released from damaged blood cells, no evidence exists to support a cause-and-effect relationship.

Other substances in salvaged blood include fat, fibrin, and microaggregates. Infusion of unprocessed blood has not been shown to be harmful in either animals or humans, possibly because of the removal of most particulate matter by standard blood filters.[142,143] Pharmaceutical contaminants, such as heparin, topical antibiotics, hemostatic agents, and biologic substances such as tissue enzymes and hormones, can be removed, but usually not completely, by washing.[144,145] Bacterial contamination during the collection and processing of autologous blood is inevitable owing to environmental organisms such as coagulase-positive and -negative staphylococci, propionibacteria, and *Corynebacterium* species. Administration of antibiotics to the patient reduces the microorganisms but does not eliminate them,[146] and complete removal of bacteria after collection also is not possible, even when the washing solution includes antibiotics.[147] There is no apparent clinical significance to such low levels of contamination. Larger bacterial counts are of more concern. Collection of blood from a contaminated site, such as that associated with spilled intestinal contents, is probably contraindicated, although some authors have argued that, if no other blood is available, such transfusions may be lifesaving and worth the risk.[148,149] Tumor cells have also been found in salvaged blood during cancer surgery; their malignant potential is unknown, and many consider cancer another contraindication.[150,151]

Finally, although it is uncommon, the collection process can be associated with fatal air embolism; such events were originally reported in association with a device that allowed reservoir contents to be pumped directly into a venous catheter, without an air detection system.[152] Although instruments with this design are no longer marketed, rare fatalities are still reported. A 1997 report cautioned that external pressure devices magnify the risk of air embolism and should never be used with perioperatively salvaged blood except if absolutely necessary and under close supervision.[153]

The collection and transfusion of intraoperatively salvaged blood has been associated with substantial reductions in allogeneic transfusions (>50%), particularly in spine surgery,[154,155] hip replacement,[156] and vascular procedures such as aortic reconstruction.[157] During cardiac surgery, the largest volume of blood that can be processed for return to the patient comes from the membrane oxygenator. Although this blood technically is not shed, in that it is removed from the

Table 30–2 **Characteristics of Perioperatively Salvaged Blood Compared with Banked Blood and Normal Patient Values***

Component	Hematocrit	Free Hemoglobin (mg/dL)	Platelet Count (per mm^3)	Coagulation Factors	Fibrin Degradation Products
Salvaged blood, unwashed	Low (25%)	Very high (≥200)	Low (100,000)	Low (35%–75%)	High (300 mg/dL)
Salvaged blood, washed	High (60%)	Low (<50)	Very low (<10,000)	Absent	Absent
Allogeneic blood (packed red blood cells)	High (60%)	Variable with age of component	Low and dysfunctional (100,000)	Low (35%–75%)	Increased
Normal patient	Normal (40%)	<5	300,000	100%	<10 mg/dL

*Typical results of laboratory tests are given. The transfusion of large volumes of salvaged blood could result in similar alterations in the recipient.

extracorporeal circuit at the end of surgery, the processing is helpful in concentrating RBCs and removing cardioplegia solution.[158,159] In liver transplantation, volumes as large as 25 units have been salvaged,[160–162] and salvage during trauma is also feasible.[147,163,164] The collection of autologous blood during cesarean section carries theoretical risks associated with transfusing amniotic fluid; however, an analysis of 139 women who received processed salvaged blood identified no increased incidence of obstetric complications.[165] Blood has also been recovered from the hemoperitoneum in association with ectopic pregnancy,[166] during radical prostatectomy,[167] and during splenectomy.[168] Intraoperatively salvaged blood has been a useful adjunct in the treatment of some Jehovah's Witnesses, whose literal acceptance of the Bible includes abstention from routine allogeneic blood transfusions. In this situation, an uninterrupted circuit between the salvaged blood processor and the patient facilitates acceptance.[169]

Postoperative Autologous Transfusion: Blood Salvage

Both canister systems and RBC processors can be used to collect postoperative blood drainage, such as that from the mediastinum after heart surgery,[170] from the peritoneal cavity after hepatic injury,[171] or from the knee or hip site after orthopedic procedures.[172] Blood salvaged from a serosal cavity has little residual fibrinogen and few platelets, and clotting is usually not a problem; therefore, the addition of anticoagulants to the collection is usually not necessary.[173] Despite the substantial levels of free hemoglobin in the salvaged blood, RBCs survive normally, as documented by studies involving radiolabeled markers.[174]

In addition to free hemoglobin, the salvaged blood may be contaminated with tissue exudate, bone, bone marrow, and other biologic and surgical materials; nevertheless, most patients tolerate the infusions well. Bioactive substances measured in the unwashed drainage include histamine, interleukin-6 and other cytokines, prostaglandins, and activated complement components; however, these levels have not been associated with transfusion reactions, and levels in patients after infusion are not significantly altered.[175–177] Similarly, methyl methacrylate (used as a cement in orthopedic surgery) and its breakdown product, methanol, can be measured in blood salvaged postoperatively from the surgical site; however, these materials have not been detected in recipients after transfusion.[178] Occasional complications do occur, however, including respiratory distress,[179] hypotension with anaphylaxis,[180] and fever.[181] The last more likely to occur when the product is collected over a long time interval (6 to 12 hours). The pathophysiology of these events remains unclear.

After open heart surgery, mediastinal blood may contain very high levels of cardiac muscle enzymes, especially creatine phosphokinase, as well as lactate dehydrogenase from hemolyzed RBCs.[141,182] The reinfusion of shed mediastinal blood can result in increased levels of these enzymes and can confound the diagnosis of myocardial infarction in the postoperative period.[183,184] The volume of RBCs actually salvaged is often small and the effect on reducing transfusions debatable. Infusion of shed mediastinal blood after cardiac operations appears to have the potential to reduce the volume of allogeneic blood required (by 1.4 units in one study).[185] In other situations, the benefit is less clear. Although the volume of postoperative drainage is often substantial in orthopedic procedures,[186,187] much of the collection is plasma and other serosanguineous fluids rather than RBCs. One study reported a mean total collection of only 55 ± 29 mL of RBCs in drains after hip surgery.[188] Orthoplasty procedures performed without cement are associated with larger perioperative blood losses, and postoperative salvage may be more effectively used in such cases.[189]

Acute Normovolemic Hemodilution

The collection of autologous blood at the start of surgery, for return to the patient at the end of the procedure, had its origins in open-heart surgery. The original goal was prevention of postoperative coagulopathies through ex vivo maintenance of a supply of platelets undamaged by exposure to the membrane oxygenator.[190,191] However, additional advantages to the intentionally created anemia were also identified. Hemodilution can contribute to a reduction in RBC loss. In simplest terms, a patient with a hematocrit of 45% and a 2 L blood loss during surgery loses roughly 900 mL of RBCs, whereas a similar patient with a hematocrit of 20% loses only 400 mL of RBCs. More elaborate mathematical modeling studies have been published that take into account the dynamic nature of the patient's RBC mass as it is affected by blood loss, fluid replacement, and blood transfusions (Fig. 30–8).[192,193] Hemodilution is probably less expensive to

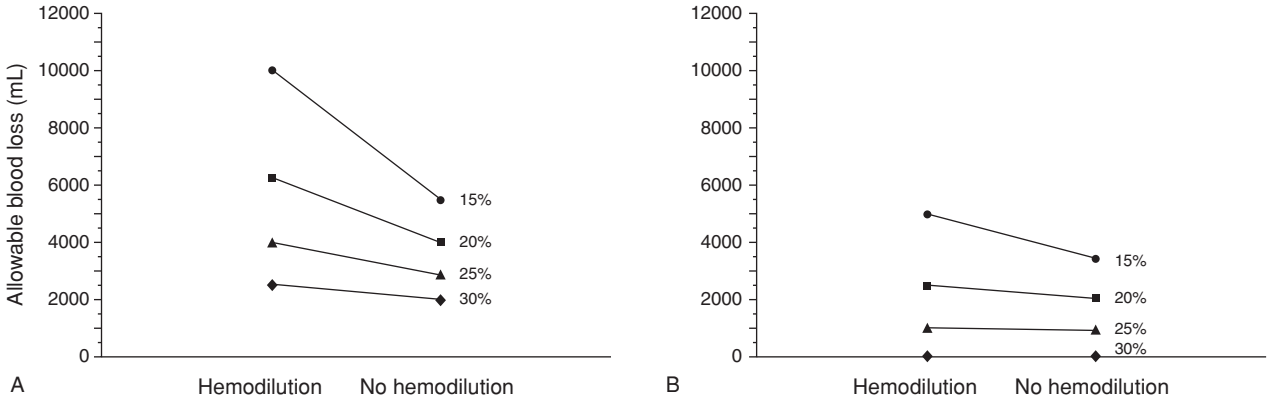

Figure 30–8 The volume of surgical blood loss (*y*-axis) that could occur before transfusion of allogeneic blood is needed in a patient of either 45% (**A**) or 30% (**B**) blood loss with a starting hematocrit and a blood volume of 5 L who either has or has not undergone isovolemic hemodilution. Each curve represents a different target hematocrit (the hemodilution end point, which is then maintained during surgery with autologous blood). (From Weiskopf RB. Mathematical analysis of isovolemic hemodilution indicates that it can decrease the need for allogeneic blood transfusion. Transfusion 1995;35:37–41. Used with permission.)

accomplish than preoperative autologous blood donation, and it may be the only option available when surgery is performed in other than elective settings.[194]

The technique involves removal of blood into standard collection bags with citrate anticoagulation (unless the patient is already heparinized) and replacement of lost volume with either crystalloids or colloids. Close monitoring of the patient's cardiovascular status is necessary during the hemodilution process. Units are stored in the operating room during surgery and reinfused as needed, in reverse order of collection, reserving the bags with the highest concentration of RBCs for the end of the procedure, after blood loss has been controlled.

In orthopedic and cardiovascular surgery, reductions in allogeneic blood use have been reported after extreme hemodilution (reduction of the patient's RBC mass by as much as 50%).[193,195] More modest hemodilution (e.g., removal of 2 units of blood at the beginning of surgery) may also be beneficial, according to some workers,[196,197] but this is not accepted by others.[192,198,199] The severity of the anemia could affect oxygen transport, although the concomitant drop in blood viscosity, and compensatory cardiac output increases, could restore oxygen delivery. However, one group has provided evidence that hemodilution may jeopardize patients at risk for myocardial infarction.[200] Further clinical studies appear necessary to resolve the continued controversy over the value of hemodilution in contemporary transfusion practice.[201,202]

Acute Normovolemic Hemodilution in Combination with Erythropoietin

Erythropoietin can be used preoperatively in conjunction with acute normovolemic hemodilution. A three-armed study looked at preoperative autologous donation (3 units) versus erythropoietin plus acute normovolemic hemodilution versus acute normovolemic hemodilution alone in patients undergoing prostatectomy. The investigation showed similar allogeneic transfusion rates with the lowest cost in the acute normovolemic hemodilution alone arm.[203] Mathematical modeling predicts preoperative erythropoietin will be most beneficial when used in conjunction with acute normovolemic hemodilution, especially in patients with small blood volumes and mild anemia.[204] This is confirmed in a study of elective open-heart surgery patients receiving erythropoietin or placebo preoperatively with intraoperative isovolemic hemodilution. In the erythropoietin group, more patients were able to have intraoperative isovolemic hemodilution, fewer patients received allogeneic blood transfusion, and the total mean transfusion per patient was lower. Further analysis showed blood loss, age, baseline hematocrit, as well as preoperative treatment with erythropoietin, to be independent predictors of the need for allogeneic blood transfusion.[205]

MULTIDISCIPLINARY APPROACH TO BLOOD MANAGEMENT

To decrease allogeneic transfusion, communication between all health care providers must occur. The likelihood of blood transfusion is decreased if the care of the patient is optimized before, during, and after surgery.

Preoperative Factors

The strongest predictor of a patient needing blood during an elective surgery is the baseline hematocrit, with other significant contributing factors being the patient's blood volume and red cell loss during the procedure.[181,206,207] Optimization of the patient's hemoglobin prior to surgery will decrease the chance of transfusion. Iron or erythropoietin may be indicated, depending on the cause of the patient's anemia. Preoperative anemia additionally increases perioperative infection and mortality, which may be a result of increase risk of allogeneic blood transfusion.[208]

The correction of impaired hemostasis should decrease blood loss and, therefore, decrease the need for transfusion. Impaired hemostasis can be corrected by discontinuing anticoagulants and antiplatelet agents in a timely manner or treating the cause of the impaired hemostasis. In a retrospective study, the frequency of blood transfusion was higher in patients without preoperative correction of primary hemostasis than in patients with correction.[209] In another retrospective study in cardiac surgery patients, preoperative use of antithrombotics (enoxaparin, clopidogrel, or GP IIb/IIIa inhibitors) increased transfusion, but uniquely preoperative

enoxaparin increased postoperative bleeding and the need for reexploration.[210]

Intraoperative Factors

Intraoperative factors to reduce allogeneic transfusion include preventing hypothermia, optimizing surgical technique, and controlling hemostasis. Surgical techniques that reduce bleeding include laparoscopic, robotic, or endovascular approaches.[211] Surgical instruments that maximize coagulation include the ultrasonic scalpel and argon beam coagulator.

Controlled Hypotension

Controlled hypotension has been shown in some small studies to decrease blood loss and transfusion in orthopedic surgery.[212,213] Combining controlled hypotension with other banked blood saving techniques, such as hemodilution, may increase the likelihood of avoiding transfusion.[214] Other studies have not shown a benefit with controlled hypotension alone.[215] The concern with controlled hypotension is that it may produce end-organ ischemia, especially in patients with atherosclerosis. The decrease in blood loss as a result of controlled hypotension may not outweigh its risk of ischemia.[211]

Normothermia

Central body temperature decreases after induction of general anesthesia, which may increase blood loss and transfusion requirements. In a small study of patients undergoing major abdominal surgery, active warming with forced air showed reduced blood loss and blood product use.[216] Two studies show conflicting results in mild hypothermia affecting blood loss in total hip arthroplasty.[217,218] Studies demonstrate conflicting results regarding blood loss and transfusion requirements with normothermia versus hypothermia cardiopulmonary bypass.[219,220] In summary, no definitive answer is available about maintaining normothermia to decrease blood loss.

Postoperative Factors

Phlebotomy

Patients in the intensive care unit have a mean blood draw of approximately 40 mL a day with a total volume of 760 mL. Patients with arterial lines have a total blood loss of approximately 900 mL. These large losses from phlebotomy contribute to increased transfusion requirements.[221]

Chapter 31

Blood Substitutes: Basic Principles and Practical Aspects

Robert M. Winslow

INTRODUCTION

Replacement of blood after acute loss has two main goals: restitution of blood volume and delivery of oxygen to tissues. In contrast, administration of red blood cells in chronic anemia or hypoxia is aimed only at restitution of oxygen delivery to tissues. Non-oxygen-carrying solutions such as saline, Ringer's lactate, albumin, dextran, and the starches are widely used to replace lost blood volume in surgery and trauma, and they can be used satisfactorily to expand blood volume. The term *red blood cell substitutes* (or just *blood substitutes*) usually refers to oxygen-carrying solutions that can both expand the blood volume and oxygenate tissues. These solutions contain a delivery system for oxygen—commonly modified hemoglobin or perfluorocarbon emulsions—and they are intended to carry out the primary function of red blood cells: transport of oxygen to tissues. To be both clinically and economically useful, such solutions should be free of antigens (i.e., not necessary to crossmatch), sterile, and have a long shelf life.

Development of a blood substitute has been an elusive goal: for centuries, an alternative to allogeneic blood for transfusion has been sought by scientists, the military, and industry. Early attempts included the use of milk, wine, gum, and red blood cell hemolysates.[1] In the modern era (since about 1965), three general types of products have been under development: modified hemoglobin solutions, perfluorocarbon emulsions, and lipid vesicle–encapsulated hemoglobin. None is as yet approved for clinical use.

The current forces driving the development of red blood cell substitutes are the perceived danger of transfusion of allogeneic blood (Table 31–1) as well as the diminishing numbers of donors of allogeneic blood. In fact, blood is safer now than it ever has been.[2] However, the aggregate risks listed in Table 31–1 are frightening to many patients, their families, and their doctors, and the demand for a safe and efficacious alternative is increasing. Beyond the risks listed in Table 31–1, in regions of the world where the frequency of human immunodeficiency virus infection is high, development of these solutions would be particularly important. Furthermore, the risks listed in Table 31–1 are for the United States; in other parts of the world, additional risks include contamination of blood with parasites, prions, other retroviruses, tick-borne illnesses, and malaria. Bacterial infections represent a growing risk as the length of time blood can be stored is increased, because the risk of contamination is proportionate to storage time.

Because of the risks of allogeneic blood transfusion, and because of the large markets that could be generated for red blood cell substitutes, considerable efforts have been expended by industry and academia to develop safe products. It is likely that red blood cell substitutes will find their way into clinical practice within the next decade. What is still not clear is what their clinical indications will be.

PRINCIPLES

It is not possible to reproduce the human red blood cell. Therefore, in designing a solution that can be used as an alternative, consideration must be given to the properties of the red cell that are critical and that can be simulated by a synthetic product. Some of these are enumerated below.

Oxygen Transport

Clearly, a red cell substitute must transport oxygen, but must a substitute transport oxygen in the same way as red blood cells do? Oxygen affinity and cooperativity of cell-free or encapsulated hemoglobin may be very different from that of red blood cells. Perfluorocarbons carry oxygen physically dissolved, rather than chemically bound, and therefore the dissociation curve is linear. Whether these factors are important, physiologically or clinically, is still not understood well, and assumptions are deeply rooted. Only extensive clinical experience will allow definite conclusions to be drawn.

Plasma Retention

The normal red blood cell half-life is about 30 days. However, the plasma half-life of cell-free hemoglobin may be only 12 to 24 hours, and that of encapsulated or surface-modified hemoglobin and perfluorocarbon emulsions may be 24 to 48 hours. Are these times clinically useful? If the effect of a red blood cell substitute is so short that a transfusion with allogeneic blood is only delayed rather than eliminated, then the usefulness of the product may be diminished.

Efficacy

It will be necessary to demonstrate efficacy for any red blood cell substitute to be used clinically. At present, it is taken as a matter of faith that a solution carrying oxygen will be more useful than one with no oxygen carrier, if it is without side

Table 31–1 **Estimated Risk of Transfusion Transmission of Viral Agents**

Virus	Risk Per Unit Transfused
HIV-1 and -2	1:2,000,000–3,000,000
Hepatitis B	1:100,000–200,000
Hepatitis C	1:1,000,000–2,000,000
HTLV-I and -II	1:641,000 (cellular components)
Parvovirus B19	1:20,000 (most recipients immune)
West Nile virus	Range 1:10,000 to 1:150 depending on region of epidemic
Bacterial contamination	1:5,000,000

Data from Klein HG. Transfusion medicine. In Blood Substitutes. Winslow R (ed). London, Elsevier, 2006, pp 17–33.

effects. However, conclusive demonstrations will be necessary because no red blood cell substitute currently being developed is without side effects. For example, if a particular substitute increases systemic pressure and vascular resistance (as many hemoglobin-based solutions do), this property could counteract any increase in oxygen transported. At present, the U.S. Food and Drug Administration (FDA) has accepted reduced use of allogeneic blood as a valid end point for clinical testing and licensure, but whether this is sufficient for widespread clinical use by physicians will not be known until products are actually on the market.[3]

Toxicity

No drug is without toxicity or side effects, and blood substitutes are no exception. Unmodified hemoglobin has vasoconstrictor properties that could limit its use in shock and trauma and in patients with ischemic disease. Lipid vesicles and perfluorocarbon emulsions stimulate macrophages to elaborate cytokines that can produce diverse effects, including fever, flulike symptoms, and thrombocytopenia.

Commercial Viability

A red blood cell substitute should be competitive with allogeneic red blood cells in effect, toxicity, and cost. The cost of providing human red blood cells for transfusion is complex and difficult to determine with accuracy, but it is probably in the range of $250 to $500 per unit. The technology required for the production of red blood cell substitutes is complex and possibly expensive, but the final cost of a product whose safety and efficacy are equivalent to those of banked blood will need to be in the same range.

PRODUCTS

Hemoglobin-Based Products

The red blood cell substitute products that have gained the most attention are based on hemoglobin, a complex molecule consisting of four polypeptide chains, each one made up of about 140 amino acids. Normally, hemoglobin is packaged in the red blood cell; when free in solution, it is fragile: the oxygen-binding iron atom tends to oxidize, it is unstable and toxic, and is excreted by the kidneys as the subunits dissociate. Over the years, the strategy for making a hemoglobin-based red blood cell substitute has been based on crosslinking hemoglobin to correct these problems.[4]

Hemoglobin has the desirable property of high capacity to bind oxygen and to release it cooperatively. However, free in solution, hemoglobin has several unique properties:

1. Its oxygen affinity is high because outside the red blood cell the allosteric effectors, 2,3-diphosphoglycerate and adenosine triphosphate, for example, are not present.
2. Its effectiveness as an oxygen carrier is limited because it dissociates into half-molecules (dimers). Haptoglobin is rapidly saturated, and excess dimers are quickly removed from the circulation by the kidney after filtration in the glomerulus.
3. Once it is filtered, a high concentration of protein in the renal tubules can cause tubular obstruction, oxidative damage, and consequent renal failure.
4. Cell-free hemoglobin binds nitric oxide, an endothelium-derived relaxing factor that may contribute to vasoconstriction.
5. Iron, when released from hemoglobin, can promote the formation of toxic oxygen radicals and bacterial growth.

Thus, to be an effective oxygen carrier in the cell-free state, hemoglobin must be chemically modified. Whether all these features must be resolved completely for a product to be useful is uncertain. Reactions currently used in the production of hemoglobin-based red cell substitutes employ chemical modification at one or more sites on the surface of the protein.[5] The dimensions and reactivity of the crosslinking reagents determine differences in the reactions. Because the function of hemoglobin in binding and releasing oxygen is intricately connected to a structural transition, it is not surprising that the oxygen half-saturation pressure and yield are variable. Even small differences among structures of the reagents can yield products with quite different properties. In addition, the conditions of the reaction are important, not only in regard to the state of ligation (i.e., oxygen saturation) but also the presence of agents or molecules that lack or compete for certain reactive sites.

A further complication of these reactions is that many nonhemoglobin proteins, copurified with hemoglobin, contain reactive groups and may also be modified to produce new, potentially toxic contaminants. It is understandable that it has been difficult to produce "pure" modified hemoglobin for toxicity studies when most processes start with relatively crude "stroma-free" hemoglobin.[6] One classification of the various types of modified hemoglobins is given in Table 31–2.

An illustrative example of a crosslinked hemoglobin is a product studied intensively by the U.S. Army and numerous academic laboratories.[7] Crosslinking of hemoglobin isolated from outdated human blood was carried out with bis(3,5-dibromosalicyl)fumarate (DBBF),[8] and it was called αα-Hb by the Army and DCLHb (proposed trade name HemAssist) by Baxter Healthcare, which produced it in commercial quantities. The reaction results in a 4-carbon covalent link between adjacent α-chains at position 99 (Lys $\alpha_1$99–Lys $\alpha_2$99) (Fig. 31–1). This covalently crosslinked hemoglobin cannot break down into subunits in the circulation and therefore cannot be excreted as filtered globin chains. Since αα-Hb was developed by the Army, its properties, toxicity,

Table 31–2 **Classes of Hemoglobin-Based Red Cell Substitutes**

Class	Examples (see also Table 31-3)	Molecular Radius* (nm)	Intravascular Persistence (h)	Oncotic Pressure	Viscosity	Vasoactivity
Crosslinked tetramers	Diaspirin crosslinked hemoglobin (DCLHb) αα-Hb rHb1.1 (Optro)	2.7	~12	Low	Low	Marked
Polymerized tetramers	HemoPure Hemolink PolyHem e	4.9	~12–24	Low	Low	Moderate
Surface-modified tetramers	Pyridoxalated hemoglobin polyoxyethylene Polyethylene glycol–hemoglobin MP4	~10	~24–48	Moderate-high	Moderate-high	Mild

*Data from Vandegriff K, McCarthy M, Rohlfs R. Winslow R. Colloid osmotic properties of modified hemoglobins: chemically cross-linked versus polyethylene glycol surface–conjugated. Biophys Chem 1997;69:23–30.

and physiologic effects have been reported in the open, peer-reviewed literature.[9] It is therefore a useful model to understand the complexities of the research and development that has taken place over the past 2 decades.

Production of αα-Hb is complex.[10] Stroma-free hemoglobin is separated from red blood cell membranes by osmotic lysis. It is then deoxygenated to achieve the proper molecular conformation for crosslinking, and the 2,3-diphosphoglycerate pocket is blocked reversibly with an allosteric effector. After crosslinking with DBBF, it is heated to pasteurize it and also to remove unreacted hemoglobin, then passed through a series of cross-flow filters. Finally, it is sterilized by filtration through a 0.2-μm filter.

The product has an oxygen equilibrium curve with an oxygen half-saturation pressure under physiologic conditions (i.e., P50) of 28 mm Hg. The degree of cooperativity (the slope of the dissociation curve) is similar to that of blood (Hill coefficient 2.62 for blood, 2.31 for crosslinked hemoglobin), and the Bohr[11] and carbon dioxide[12] effects are essentially intact.

Based on its oxygen equilibrium curve, this product should have in vivo oxygen transport properties similar to those of whole blood; its oxygen equilibrium curve is closer to that of red blood cells than that of other types of red blood cell substitutes (Fig. 31–2). The intravascular persistence is markedly extended in the rat: uncrosslinked hemoglobin has a half-life of about 1.2 hours, and crosslinked hemoglobin has a half-life of about 4.3 hours. In the rabbit, the persistence is longer, approximately 16 hours for crosslinked hemoglobin, for the monkey about 14 hours, and for the pig about 7 hours.[13] No doubt exists that cell-free hemoglobin transports oxygen. Many studies in the literature have demonstrated the ability of hemoglobin solutions to resuscitate animals in lethal hemorrhagic shock.[4]

DCLHb was studied extensively in clinical trials. However, the product was found to be severely vasoactive; it raised blood pressure and increased systemic and pulmonary vascular resistance.[14,15] Phase III clinical trials were disappointing; trials in trauma[16] and in stroke[17] both showed reduced survival in patients who received the product.

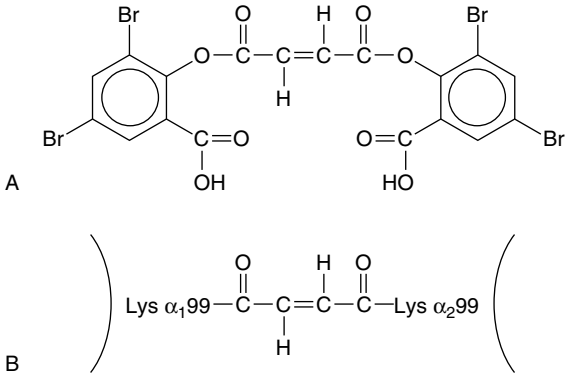

Figure 31–1 Structure of the crosslinker, bis(2,3-dibromosalicyl) fumarate (DBBF; **A**) and crosslinked hemoglobin (**B**). The brominated acetyl groups of the DBBF are leaving groups in the reaction, which results in a 4-carbon bridge between the two α-chain polypeptide subunits of hemoglobin.

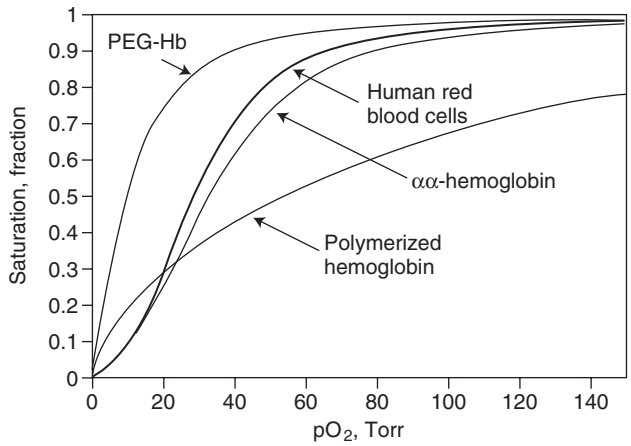

Figure 31–2 Oxygen equilibrium curves for some representative red cell substitutes. Note the large difference between the curves for PEG-Hb, ***O***-raffinose polymerized hemoglobin, and red blood cells.

Closely related to αα-hemoglobin is a recombinant product (rHb1.1, Optro) produced in *Escherichia coli*.[18] Starting material for hemoglobin modification can also be produced in transgenic animals.[19] Hemoglobin additionally can be polymerized by means of various polyfunctional reagents to yield molecules with markedly increased molecular weights. One example is human hemoglobin, reacted first with pyridoxal 5′-phosphate and then polymerized with glutaraldehyde.[20] This product has a reduced colloidal osmotic (oncotic) pressure and longer intravascular persistence compared with smaller molecules, but the polymerization reaction is notoriously difficult to control.[21,22]

Large molecules, such as hemoglobin coupled to polyethylene glycol,[23,24] starch,[25] or dextran[26] may have prolonged plasma retention times, may have reduced interactions with the reticuloendothelial systems and may extravasate less readily than smaller molecules. The same result can be achieved by directly linking hemoglobin molecules to create large polymers[27] or by use of naturally occurring large polymers such as found in the earthworm.[28] In addition to reduced extravasation, these large molecules have reduced diffusivity in the plasma, which in turn reduces vasoconstriction by limiting oxygen supply to arterial walls.

Liposome-Encapsulated Hemoglobin

Because hemoglobin is normally packaged inside a membrane, it seems intuitively correct that encapsulated hemoglobin would be the ultimate solution to the red blood cell substitute problem. In 1957, Thomas Chang reported the use of microencapsulated hemoglobin as artificial red blood cells.[29] Since that time, dramatic results have been reported in the complete exchange transfusion of laboratory animals,[30,31] but progress toward development of an artificial red blood cell for human use has been slow because of difficulties with reticuloendothelial and other macrophage stimulation.[32] Other problems include maintaining sterility, limiting hemoglobin oxidation, and the economics of large-scale production.

In the years that have followed Chang's initial descriptions of encapsulated hemoglobin, much work with lipid vesicles (liposomes) has been done. Liposomes have served as models for understanding natural cell membranes. They also have been used investigationally as vehicles for gene transfer, as targeted carriers, for pharmacologic agents, and even as lubricants for degenerated joint surfaces. The most extensively studied liposomes used to encapsulate hemoglobin are composed of phospholipid in combination with cholesterol and other lipids that confer flexibility and stability, such as ganglioside GM_1 or cholesterol.[33] When injected into animals, such liposomes are rapidly coated with immunoglobulin G, albumin, and other opsonins.[34] Newer formulations include the use of surface components such as polyethylene glycol or dextran, which can stabilize the liposomes in the circulation.[35] Hemoglobin vesicles (HbV) are being developed in Japan and may enter clinical trials soon.[36]

The limitations to the development of liposome-encapsulated hemoglobin as a red blood cell substitute are difficulties in stabilizing the final product and the massive scale that would be required to produce a commercial product. The size of most liposome particles is approximately 0.2 to 1.0 μm, too large to be filter-sterilized. In addition, neither the liposome nor its hemoglobin contents can withstand pasteurization temperature without some type of stabilizer. Other potential approaches to the solution of these problems could include polymerizable phospholipids[37] and other polymers.[38]

Perfluorocarbon-Based Products

Fluosol-DA (Fluosol, Green Cross Corp., Osaka, Japan) was approved for marketing by the FDA for use in coronary angioplasty in 1990, but manufacture was discontinued in 1995 and the product was withdrawn for multiple reasons: efficacy was marginal, the product was technically difficult to use, and new developments in coronary angioplasty (the indication for which it was approved) made its use obsolete. Newer perfluorocarbon emulsions were developed by industry that carried more oxygen than did previous products[39]; however, regardless of oxygen capacity, a fundamental difference exists between perfluorocarbon- and hemoglobin-based red blood cell substitutes: oxygen is transported by perfluorocarbons as dissolved gas, whereas hemoglobin carries oxygen chemically bound to the protein itself. Because of the nature of the binding of oxygen by hemoglobin, oxygen is not released until hemoglobin reaches regions of the circulation where pO_2 is low (i.e., ischemic tissue). In contrast, the release of oxygen from perfluorocarbon emulsions is linear with pO_2, which means that the bulk of the dissolved oxygen will be lost from the circulation before the product reaches ischemic or hypoxic tissue. One product, Oxygent (Alliance Pharmaceutical Corp.) is an emulsion of perflubron and egg yolk phospholipid that contains about five times more fluorocarbon than Fluosol-DA does and therefore five times more dissolved oxygen. Oxygent underwent extensive phase 2 clinical testing but in critical phase 3 trials of hemodilution and perioperative autologous blood collection, there was a higher incidence of stroke in treated patients compared with controls.[40] Development of Oxygent was subsequently scaled back, and it is questionable whether trials will continue.

SAFETY

Demonstration of safety of red blood cell substitutes is a critical issue, because the risks of transfusion of allogeneic blood are well known (see Table 31–1). To be used, a substitute should be at least as safe as red blood cells, unless a decisive therapeutic advantage can be demonstrated.

In a review of almost a century of clinical trials with red blood cell substitutes, reported side effects involved renal dysfunction and systemic symptoms (fever, chills, nausea, headache, flushing, vomiting, allergic reactions, tachycardia, bradycardia, hypertension, rigors, low back pain, chest pain, abdominal pain, decreased platelets, and increased partial thromboplastin time).[4] Many of these effects could be explained by the depletion of nitric oxide, in the case of hemoglobin-based products, or by stimulation of macrophages, in the case of liposomes or perfluorocarbon emulsions. Many are smooth muscle effects, and some involve macrophages and platelets. Preclinical animal studies with hemoglobin-based solutions clearly have not been completely successful in predicting human reactions to the products.[41]

Cell-free hemoglobin is widely distributed in the tissues after administration. Studies of the distribution of cross-linked hemoglobin in the intact animal show that significant amounts of hemoglobin are retained in the kidney, spleen, liver, adrenal gland, lung, heart, brain, and muscle well after

any hemoglobin is detected in plasma.[42–44] Thus, cell-free hemoglobin is distributed in almost every tissue of the body, and there could be unpredictable or unknown toxic effects. Extensive histologic studies were carried out in animals after exchange transfusion and summarized.[4]

The effect of cell-free hemoglobin of most concern is its known ability to cause vasoconstriction and hypertension. This vasoconstriction can be mediated in part by the reaction of hemoglobin with nitric oxide, an endothelium-derived relaxing factor.[45] Nitric oxide is synthesized from arginine in endothelial (and other) cells by an enzyme, nitric oxide synthase, which produces nitric oxide and citrulline. It binds to a heme group in guanylate cyclase that activates cyclic guanosine monophosphate. Nitric oxide diffuses rapidly out of endothelial cells into the vessel lumen, the interstitial space, and smooth muscle cells, where it binds to a heme group in guanylate cyclase, activating cyclic guanosine monophosphate and moving calcium from the unbound to bound state. The result is smooth muscle relaxation. Nitric oxide also stimulates platelets and polymorphonuclear leukocytes and macrophages. Hemoglobin binds nitric oxide very tightly, more tightly in fact than it binds oxygen, whether hemoglobin is in the red blood cell or free in solution.[46] The reaction is virtually irreversible. Whether this interaction of hemoglobin with nitric oxide will limit clinical usefulness of hemoglobin-based red blood cell substitutes remains to be determined.

Nitric oxide binding by cell-free hemoglobin is not the sole explanation for its vasoconstrictor activity, however.[47] In addition to its effect as a scavenger of nitric oxide, cell-free hemoglobin may induce vasoconstriction by disrupting normal autoregulation of vascular tone. In other words, it may make oxygen so readily available to regulatory arterioles that reflexive vasoconstriction could occur that paradoxically limits blood flow.[48,49] This concept is suggested by direct observation in the microcirculation[50] and has led to new design strategies for cell-free red blood cell substitutes.[51] Perfluorocarbon emulsions have the most extensive history of use in humans. Fluosol-DA was approved by the FDA for use in coronary angioplasty and therefore was given to many human patients. Similar formulations have been used on the battlefield in China and Afghanistan, although data are generally not available. Perfluorocarbon emulsions have also been tested in humans as imaging agents. The principal toxicity of perfluorocarbon emulsions appears to be in their stimulation of macrophages.[52,53] This can result in pulmonary hypertension and elaboration of thromboxane in swine and could lead to nonspecific symptoms such as fever, chills, and flulike symptoms in humans.

Biocompatibility studies with liposome-encapsulated hemoglobin have been generally favorable,[31] but such products tend to be removed from the circulation by the phagocytic cells of the reticuloendothelial system.[54] This situation leads to significant enlargement of the liver and spleen. Current research is aimed at prolongation of the intravascular persistence to minimize this problem.[55]

EFFICACY

It seems intuitively obvious that a plasma expander that carries oxygen would be superior to one that does not, and experimental proof of this concept should be relatively straightforward. However, the problem of efficacy can be appreciated by considering the difficulties in showing efficacy for red blood cell transfusions. The problem is a lack of clear end points: no single measure of oxygen transport is accurate and easily obtainable. It may be possible to show improved clinical outcome after transfusion of red blood cells to patients with extremely low hematocrits, but the bulk of allogeneic blood is given intraoperatively in response to blood loss and hemodynamic instability, not severe anemia.

Most demonstrations of efficacy in animals have been either by exchange transfusions with test material or by resuscitation from shock. Resuscitation from shock is exceedingly complex, however, and the most urgent requirement is for volume replacement.[56] Clinical trials involving trauma patients are particularly difficult to design because of the problems of controls and informed consent. Future clinical trials will most likely be aimed at, for example, reduced use of allogeneic blood, rather than at specific oxygen transport parameters, which may be controversial, at best. For example, one trial with Fluosol-DA during surgical procedures showed that its use did not reduce the need for allogeneic blood transfusions in the postoperative period.[57]

CLINICAL TRIALS

Early trials with various cell-free hemoglobin solutions were reviewed and showed an array of side effects involving every organ of the body.[4] However, most of these are mild or reversible, and only one death in more than 211 patients was reported in the early literature; this patient was terminally ill and would likely have died even without the administration of hemoglobin.[58]

Certain red blood cell substitute products are in various stages of advanced clinical trials (Table 31–3). The greatest concern for hemoglobin-based products is that the known vasoactivity of the solutions could lead to hypertension or underperfusion of ischemic tissue. A major concern with

Table 31–3 **Red Cell Substitutes in Clinical Trials**

Product (Manufacturer)	Composition	Indication	Clinical Testing Stage
Hemopure (BioPure)	Glutaraldehyde–polymerized bovine hemoglobin	Local perfusion	II
PolyHeme (Northfield)	Glutaraldehyde–polymerized human hemoglobin	Trauma	III
Hemospan (Sangart)	PEG–human hemoglobin	Elective surgery	III
Synthetic blood	Perfluorocarbon emulsion	Sickle cell anemia	II

perfluorocarbon emulsions appears to be thrombocytopenia.[59] No liposome-based product has yet been approved for use in human trials.

At this time, trauma trials are underway with Northfield's PolyHeme,[60] but advanced trials of several hemoglobin products, including HemAssist (Baxter),[16,17] HemoPure (Biopure), and Hemolink (Hemosol) have been abandoned. One new product, Sangart's Hemospan, based on PEG-modified human hemoglobin,[61] has successfully completed phase 2 testing.

IMPLICATIONS AND FUTURE APPLICATIONS

Potential Clinical Applications

The need for red blood cell substitutes to replace all use of allogeneic blood is both unnecessary and naive. The red blood cell substitute candidates now being developed will probably be used initially in surgical procedures to provide a margin of safety and perhaps to reduce or eliminate transfusions of 1 to 2 units of allogeneic blood.

Many clinical applications in addition to hemodilution for the products now being developed will be targeted by industry (Table 31–4). Applications for perfluorocarbon emulsions other than as red blood cell substitutes could surpass their use in trauma, surgery, and shock. For example, emulsions have been shown to increase the radiosensitivity of solid tumors,[62] to be excellent nuclear magnetic resonance and ultrasound imaging agents,[63] to be capable of removing gaseous microemboli during cardiopulmonary bypass,[64] and to measure tissue pO_2.[65]

Availability in the Future

It seems unlikely that cell-free hemoglobin as a red blood cell substitute with vasoactive effects will be accepted broadly by clinicians. Indeed, vasoconstriction is a hallmark of the shock state, but hemoglobin solutions with reduced vasoactivity could be successful. Perfluorocarbon emulsions may be used as imaging enhancers, liquid-breathing agents, or adjuncts to radiotherapy of solid tumors. The low cost and simplicity of production of perfluorocarbon emulsions are favorable qualities for commercialization.

Liposome-encapsulated hemoglobin may be the ultimate solution to the red blood cell substitute problem, but to be successful, an inexpensive and simple process has to be developed, and any problems of reticuloendothelial blockade and engorgement of organs such as liver and spleen must be thoroughly studied and understood.

The present commercial climate is such that few, if any, of these products are being used in scientific studies that can be evaluated in the peer-reviewed literature until they are approved for use by the FDA. This situation has retarded development in the past and is likely to do so in the future.[41]

Table 31–4 Potential Clinical Applications for Red Cell Substitutes

Hemodilution, elective surgery
Trauma
Chronic anemia
Ischemic disease (angioplasty, stroke)
Red cell incompatibility (rare blood types)
Extracorporeal circulation (bypass)
Cell culture media
High-blood-use surgery
Cardioplegia
Tumor oxygenation
Organ transplantation
Bone marrow transplantation support
Sickle cell anemia
Oxygen delivery and circulation research

A. Transfusion in Specific Clinical Settings

Chapter 32

Red Cell Transfusion in Perioperative and Critically Ill Patients

Paul C. Hébert • Alan Tinmouth • Jeffrey L. Carson

RED CELL UTILIZATION IN PERIOPERATIVE AND CRITICAL CARE

Despite concerns regarding transfusion-transmitted viruses, allogeneic red blood cell (RBC) transfusions clearly save lives in the perioperative and critical care setting. Indeed, hemoglobin binds and transports more than 98% of all oxygen delivered to peripheral tissues. Therefore, RBC transfusions are a lifesaving measure that maintain oxygen transport during severe anemia. Severe anemia has been shown to increase mortality rates from 1.3%, when hemoglobin concentrations exceed 120 g/L, to more than 33%, when hemoglobin concentrations are less than 60 g/L[1] in perioperative patients refusing allogeneic RBC transfusions. A limited number of studies describe the overall patient population requiring allogeneic RBC transfusions.[1–3] In a 1992 survey conducted in 61 Toronto area hospitals, 65% of RBCs transfused were administered to patients undergoing operative procedures categorized as digestive and abdominal, cardiovascular, and musculoskeletal.[2] Brien and colleagues[3] documented that 56% of all allogeneic RBCs were administered to surgical patients while a study by Ghali[1] documented that 69% of RBCs were transfused into surgical patients. In general, cardiovascular surgical procedures, orthopedic procedures (e.g., total hip and knee replacement), and selected gynecologic (e.g., radical hysterectomy) and urologic procedures (e.g., radical prostatectomy) were noted to have a high proportion of patients requiring allogeneic RBC transfusions.[2] In patients undergoing elective aortic aneurysm repair and coronary revascularization, up to 50% to 80% received RBCs.[2] In a recent study examining transfusion practice in critically ill patients, the authors documented that an average of 25% of all patients receive RBC transfusions, with a range of 20.4% to 53.4%.[4] Thus, albeit difficult to quantify, perioperative and critical care still consume a large proportion of the blood supply.

Allogeneic RBC transfusions are complex biological products prepared from donated blood and may be considered unique in many respects compared with other health interventions. Decisions concerning the use of RBC transfusion in the treatment of anemia and hemorrhage require a clear understanding of both risks and benefits of both the condition and treatment of patients. Although we have developed a much clearer appreciation for the infectious and immunomodulatory risks of RBC transfusion over the past two decades, the risks of anemia in many clinical settings and the benefits of RBC transfusion are still inadequately characterized. It is commonly assumed that the most significant risk associated with anemia is the harm resulting from the decreases in oxygen-carrying capacity and plasma volume. The development of adverse health consequences from anemia will, in part, depend on the capacity of the individual patient to compensate for these changes. The benefit of transfusion is derived from the capacity of donor RBCs to correct these deficits and possibly provide additional benefits such as increasing oxygen delivery to supranormal ranges. Such a framework highlights the concept that RBC transfusions have a number of tradeoffs between risks and benefits. With the exception of patients who refuse blood for religious reasons, it is impossible to separately analyze these competing risks and benefits for patients outside a randomized clinical trial.

ADAPTATION TO ANEMIA AND TRANSFUSIONS

In anemia, O_2-carrying capacity is decreased but tissue oxygenation is typically preserved, even at hemoglobin levels well below 100 g/L. Following the development of anemia, adaptive changes occur, including a shift in the oxyhemoglobin dissociation curve, hemodynamic alterations, and microcirculatory alterations. The shift to the right of the oxyhemoglobin dissociation curve in anemia is primarily the result of increased synthesis of 2,3-diphosphoglyerate (DPG) in red cells.[5–18] This rightward shift enables more O_2 to be released to the tissues at a given pO_2, offsetting the effect of reduced O_2-carrying capacity of the blood. In vitro studies have also demonstrated rightward shifts in the oxyhemoglobin dissociation curve with decreases in temperature and pH.[19] Although clinically important shifts have been documented in a number of studies, measurements of hemoglobin O_2 saturation are generally performed on arterial specimens processed at standardized temperatures and pH. Therefore, current measurement techniques will not reflect O_2-binding affinity in the patient's microcirculatory environment, which is potentially affected by temperature, pH, and some disease processes.[19,20]

Several hemodynamic alterations also occur following the development of anemia. The most important determinant of cardiovascular response is the patient's volume status or, more specifically, left ventricular preload. The combined effects of hypovolemia and anemia often occur as a result of blood loss. Tissue hypoxia or anoxia may occur as a result of either decreased blood flow (stagnant hypoxia) or decreased O_2-carrying capacity (anemic hypoxia).[21–24] The body primarily attempts to preserve O_2 delivery to vital organs through increased myocardial contractility and heart rate as well as increased arterial and venous vascular tone mediated through increased sympathetic activity. In addition, central and regional reflexes redistribute organ blood flow. The adrenergic system plays an important role in altering blood flow to and within specific organs. The renin-angiotensin-aldosterone hormone system is stimulated to retain both water and sodium. Losses ranging from 5% to 15% in blood volume result in variable increases in resting heart rate and diastolic blood pressure measures. Orthostatic hypotension is often a sensitive indicator of relatively small losses in blood volume that are not sufficient to cause a marked blood pressure fall. Larger losses result in progressive increases in heart rate and decreases in arterial blood pressure accompanied by evidence of end-organ hypoperfusion. The increased sympathetic tone diverts an ever decreasing global blood flow or cardiac output away from the splanchnic, skeletal, and skin circulation toward the coronary and cerebral circulation. Once vital organ systems such as the kidneys, central nervous system, and heart are affected, the patient is considered in hypovolemic shock. Although the American College of Surgeons' Committee on Trauma[25] categorizes the cardiovascular and systemic response to acute blood loss according to degrees of blood loss, many of these responses are modified by patient characteristics such as age, comorbid illnesses, pre-existing volume status and hemoglobin values, use of medications having cardiac (i.e., β-blockers) or peripheral vascular effects (i.e., antihypertensives), and rapidity of blood loss.

The compensatory changes in cardiac output have been the most thoroughly studied cardiovascular consequence of normovolemic anemia. When intravascular volume is stable or increased following the development of anemia (as opposed to hypovolemic anemia and shock), increases in cardiac output have been consistently reported. Indeed, an inverse relationship between hemoglobin levels (or hematocrit) and cardiac output has been clearly established in well-controlled laboratory studies.[26–32] Similar clinical observations were made in the perioperative setting[33–40] and in chronic anemia.[26,41–43] Recently, the rise in cardiac output with progressive decreases in hemoglobin concentrations was clearly established in healthy awake volunteers (Fig. 32–1).[43a] These adaptive responses observed in clinical studies may be affected by major comorbid illnesses such as cardiac disease and age, lack of appropriate control patients, and significant weaknesses in study design. Researchers have also attempted to determine the level of anemia at which cardiac output begins to rise. Reported thresholds for this phenomenon identified in primary clinical and laboratory studies range from 70 to 120 g/L.[26,28,44–47]

Two major mechanisms are thought to primarily modulate the physiologic processes underlying the increased cardiac output during normovolemic anemia: (1) reduced blood viscosity and (2) increased sympathetic stimulation of the cardiovascular effectors.[24,29,48–50] Blood viscosity exerts major effects on both preload and afterload, two of the major determinants of cardiac output[48,51,52] while sympathetic

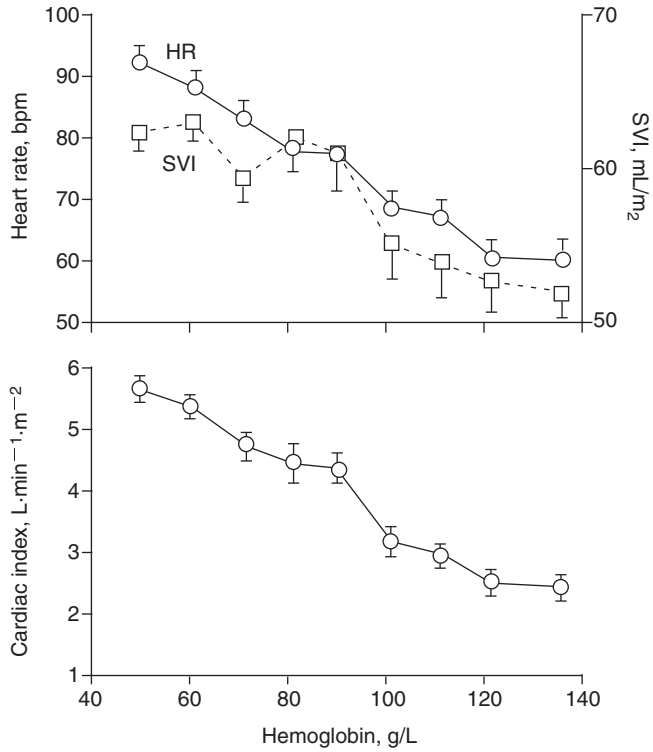

Figure 32–1 Acute isovolemic reduction of hemoglobin concentration to 50 g/L increased heart rate (HR). (From Weiskopf RB, Viele MK, Feiner J, et al. Human cardiovascular and metabolic response to acute, severe, isovolemic anemia. JAMA 1998;279:217–221.)

stimulation primarily increases the two other determinants: heart rate and contractility. As opposed to hypovolemic anemia, the effects of blood viscosity appear to predominate in this setting.[51–53]

There are complex interactions between blood flow, blood viscosity, and cardiac output. In vessels, blood flow alters blood viscosity, and in turn blood viscosity modulates cardiac output. Under experimental conditions in rigid hollow cylinders, blood flow is directly related to the diameter and the pressure difference between the ends of the cylinder and inversely related to its length and the blood viscosity (Poiseuille-Hagen law).[24,48,49] Blood is not a Newtonian fluid (i.e., its viscosity will change according to blood flow velocity). Thus, viscosity is highest in postcapillary venules, where flow is lowest, and viscosity is lowest in the aorta, where flow is highest. In postcapillary venules, there is a disproportionate decrease in blood viscosity as anemia worsens, and as a consequence, venous return is significantly increased. If cardiac function is normal, the increase in venous return or left ventricular preload will be the most important determinant of the increase in cardiac output during normovolemic anemia. Interestingly, if viscosity is maintained during anemia using colloidal solutions of known high viscosity other than red cells, these cardiovascular effects are attenuated.[51] Decreased left ventricular afterload, another cardiac consequence of decreased blood viscosity, may also be an important mechanism for the increase in cardiac output as anemia worsens.[51]

Investigators[29,44,51,52,54–56] have observed alterations not only in viscosity during anemia but also in sympathetic stimulation. Reviews and guidelines indicate that anemia also results in an increase in heart rate.[28,48,57] This physiologic response

is thought to be predominantly mediated through aortic chemoreceptors[29,50] and release of catecholamines.[27,29,54,58,59] However, primary laboratory studies,[59,60] studies of perioperative normovolemic hemodilution,[33–35] and studies of chronic anemia[41,42] have not consistently demonstrated significant increases in heart rate following moderate degrees of anemia. In a detailed review by Spahn and colleagues,[48] there appeared to be some differences in species responses as well as between awake and anesthetized patients. In three poorly controlled studies in children, there are conflicting results as to whether the increase in cardiac output is mostly a consequence of increased heart rate[42,61] or stroke volume.[62] In summary, the increase in cardiac output is more dependent on stroke volume and to a lesser extent on heart rate in most clinical settings. If indeed increased heart rate does occur from normovolemic anemia, one of its major consequences will be to adversely affect coronary blood flow by decreasing diastole, the time when the left ventricular myocardium is perfused.[63,64]

The sympathetic stimulation may also result in increased cardiac output through enhanced myocardial contractility[65,66] and increased venomotor tone.[29,67] The effects of anemia on left ventricular contractility in isolation have not been clearly determined given the complex changes in preload, afterload, and heart rate. Only one before and after hemodilution study used load-independent measures to document increased left ventricular contractility.[66] Chapler and Cain[29] have summarized several well-controlled studies indicating that venomotor tone is increased and that it results from stimulation of the aortic chemoreceptors. If sympathetic stimulation is significant in the specific clinical setting, then contractility will be enhanced from stimulation of the β-adrenergic receptors.[48,54,56,65]

Under experimental laboratory conditions, several investigators[58,68–72] have observed significant increases in coronary blood flow directly related to the degree of normovolemic anemia. In addition, these same studies do not appear to demonstrate significant shifts in the distribution of coronary flow between endocardium and epicardium in a normal coronary circulation during moderate degrees of anemia. Furthermore, significant alterations in flow distribution between major organs following acute hemodilution have been documented.[28,29,53,60,68,72–76] Disproportionate increases in coronary and cerebral blood flow were noted during observation of simultaneous decreases in blood flow to the splanchnic circulation.

The inverse relationship between cardiac output and hemoglobin levels has led investigators to determine the hemoglobin level that maximizes O_2 transport. Richardson and Guyton,[77] evaluating the effects of hematocrit on cardiac performance in a canine model, established optimal O_2 transport to occur between hematocrit values of 40% and 60%. Others determined maximum O_2 delivery to be in the lower end of the range, at a hematocrit value of 40% to 45% (132 to 150 g/L).[68,72,78] However, one of the most widely quoted studies addressing this topic from Messmer and colleagues[45] found that optimal O_2 transport occurred at hematocrit values of 30% (hemoglobin = 100 g/L). Unfortunately, global indices of optimal O_2 delivery will mask any differences in blood flow between specific organs.[53,58,79,80] In addition, attempting to identify a single optimal hemoglobin that maximizes O_2 delivery neglects consideration of the large number of factors interfering with adaptive mechanisms in patients other than healthy young adults with anemia.

Will the transfusion of allogeneic red cells reverse any adaptive response to acute or chronic normovolemic anemia? Given that O_2-carrying capacity is not impaired in the red cell storage process and that blood viscosity is restored following a transfusion, the cardiovascular consequences should be reversed if there has been no irreversible ischemic damage. However, the storage process alters red cell properties, which in turn may impair flow and O_2 release from hemoglobin[5,14] in the microcirculation.

NATURAL HISTORY OF UNCORRECTED ANEMIA IN PATIENTS

Numerous laboratory experiments indicate that extreme hemodilution is well tolerated in healthy animals. Animals subjected to acute hemodilution tolerate decreasing hemoglobin concentration down to 50 to 30 g/L, with ischemic electrocardiographic changes and depressed ventricular function occurring, respectively, at these levels of hemoglobin concentration.[81] However, acute hemodilution is less well tolerated in experimental animal models of coronary stenosis, with ischemic electrocardiographic changes and depressed cardiac function occurring at hemoglobin concentrations between 70 and 100 g/L. Human data regarding the limits of anemia tolerance are inadequate and often conflicting. For example, Leung and colleagues[82] found electrocardiographic changes that may have been indicative of myocardial ischemia in 3 of 55 conscious resting volunteers subjected to acute isovolemic hemodilution to hemoglobin concentration of 50 g/L.

Although the above experimental data provide insight to the human physiologic response to acute anemia, they are of limited applicability in the perioperative setting, where many of the factors that influence oxygen consumption including muscle activity, body temperature, heart rate, sympathetic activity, and metabolic state are altered. Instead, it is more appropriate to determine the risk of withholding RBC transfusions in the perioperative setting. From a systematic review completed for the Canadian Guidelines on red cells, Hébert et al[83] identified numerous reports of severe anemia being well tolerated in surgical patients.[84–96] Additional reports or case series[94,97–99] describe successful outcomes in patients with chronic anemia as a result of renal failure. Finally, descriptive studies in patients refusing red cell transfusion[85–87,93] and from regions experiencing limited blood supplies[88,100] have demonstrated that patients can survive surgical interventions with hemoglobin levels as low as 45 g/L.

In some of these studies, there appears to be an association between preoperative hemoglobin concentrations, intraoperative estimated blood loss, and postoperative mortality.[86,87] Indeed, there were no reported deaths in more than 100 major elective surgical patients when preoperative hemoglobins were greater than 80 g/L and the estimated blood loss was less than 500 mL. In a single center series of 542 Jehovah's Witness patients undergoing a cardiac surgical procedure, the overall mortality was 10.7% and only 2.2% of the deaths observed were considered to be a direct consequence of anemia. More recently, Viele and Weiskopf[96] identified 134 Jehovah's Witness patients who had a hemoglobin concentration less than 80 g/L or hematocrit below 24% who were treated for various medical and surgical conditions without the use of blood or blood components. There were 50 reported deaths, 23 of which were attributed primarily

or exclusively to anemia, defined as deaths with hemoglobin concentration below 50 g/L. For those patients dying of anemia, 60% were more than 50 years old. However, in 27 survivors with hemoglobin concentration below 50 g/L, 65% were less than 50 years of age. While publication bias must be kept in mind when examining these data, young healthy patients may survive without transfusion at hemoglobin concentrations in the range of 50 g/L. From these data, it is clear that extreme anemia is tolerated in the perioperative setting but also appears to increase the risk of death. However, these observations should not be interpreted as support for a restrictive or conservative transfusion strategy, especially since most of the literature related to tolerance of anemia has not explored patient characteristics that predispose patients to adverse outcomes from moderate to severe anemia.

ANEMIA IN HIGH-RISK GROUPS

A number of risk factors for adverse outcomes associated with anemia have been identified in clinical practice guidelines[57,101,102] and reviews.[28,30,49] Anemia is believed to be less well tolerated in older patients, the severely ill, and patients with clinical conditions such as coronary, cerebrovascular, or respiratory disease. However, the clinical evidence confirming that these factors are independently associated with an increased risk of adverse outcome is lacking. One small case control study following high-risk vascular surgery suggests an increase in postoperative cardiac events with increasing severity of anemia.[90] In perioperative[103] and critically ill patients[104] two large cohort studies have documented that increasing degrees of anemia were associated with a disproportionate increase in mortality rate in the subgroup of patients with cardiac disease. In 1958 Jehovah's Witness patients,[103] the adjusted odds of death increased from 2.3 (95% CI of 1.4 to 4.0) to 12.3 (95% CI of 2.5 to 62.1) as preoperative hemoglobin concentrations declined from the range of 100 to 109 g/L to 60 to 69 g/L in patients with cardiac disease (Fig. 32–2). There was not a significant increase in mortality in noncardiac patients with comparable levels of anemia. In a separate study of critically ill patients,[104] patients with cardiac disease and hemoglobin concentrations less than 95 g/L also had a trend toward increased mortality (55% vs 42%, $P = 0.09$) compared with anemic patients with other diagnoses. Although both cohort studies were retrospective and may not have controlled for a number of important confounders, the evidence suggests that anemia increases the risk of death in patients with significant cardiac disease. Severity of illness also appears to be a risk factor in the critically ill.[86,104] Two retrospective studies document that the degree of blood loss contributes to perioperative mortality.[86,104] However, no studies have examined the independent contribution of age, cerebrovascular disease, and respiratory disease to an increased mortality risk in anemic patients. This relationship may well be complex given that age and cerebrovascular disease are risk factors associated with coronary artery disease. Smoking and related respiratory diseases may have similar associations to cardiac disease. Therefore, the association between anemia and increased rates of adverse outcomes in these patients can best be described as speculative at this time.

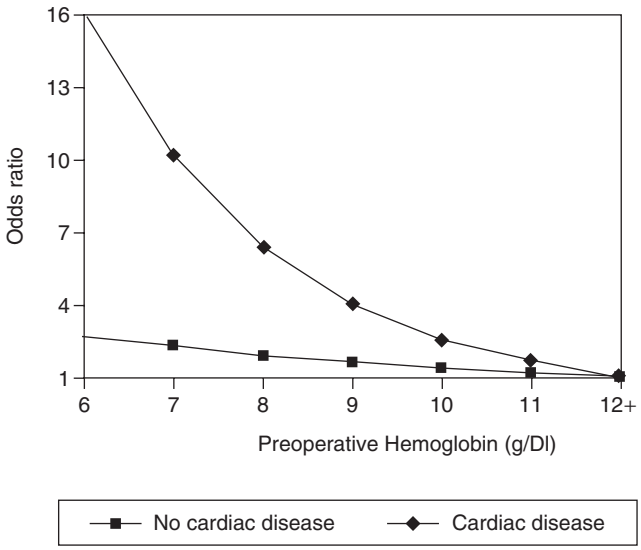

Figure 32–2 Adjusted odds ratio for mortality by cardiovascular disease and preoperative hemoglobin. (Adapted from Carson JL, Duff A, Poses RM, et al. Effect of anemia and cardiovascular disease on surgical mortality and morbidity. Lancet 1996;348:1055–1060.)

THE BENEFITS (AND POTENTIAL RISKS) OF TRANSFUSION

Four large observational studies specifically designed to compare clinical outcomes at varying hemoglobin concentrations in transfused and nontransfused patients were conducted in various clinical settings. In the first, Hébert et al[104] used a combined retrospective and prospective cohort design to examine 4470 critically ill patients admitted to six Canadian tertiary level intensive care units (ICUs) during 1993. In patients with cardiac diagnoses (ischemic heart disease, arrhythmia, cardiac arrest, and cardiac and vascular surgical procedures) there was a trend toward increased mortality when hemoglobin concentrations were less than 95 g/L. Furthermore, analysis of a subgroup of 202 patients with anemia, an Acute Physiology and Chronic Health Evaluation II (APACHE II) score greater than 20, and a cardiac diagnosis revealed that transfusion of 1 to 3 units or 4 to 6 units of RBCs was associated with a significantly lower mortality rate when compared with patients who did not receive transfusion (55% no transfusions vs 35% 1 to 3 units or 32% 4 to 6 units, respectively, $P = 0.01$). Although the design of the analysis attempted to control for the confounding influence of disease severity, it is quite possible that the complex interrelationship between disease severity, the number of transfusions, and the degree of anemia may have resulted in a spurious association between a cardiovascular diagnosis and the reported mortality risk with anemia.

Wu and associates[105] retrospectively studied Medicare records of 78,974 patients older than age 65 who were hospitalized with a primary diagnosis of acute myocardial infarction. The authors then categorized patients according to their hematocrit on admission. Although anemia, defined in the study as a hematocrit less than 39%, was present in nearly half the patients, only 3680 patients received an RBC transfusion. Lower admission hematocrit values were associated with increased 30-day mortality, with mortality rate approaching 50% among patients with a hematocrit of 27% or lower who did not receive an RBC transfusion. Unfortunately, this study did not have any data on nadir hemoglobins and their

relationship to mortality. Interestingly, whereas RBC transfusion was associated with a reduction in 30-day mortality for patients who received at least one RBC transfusion if their admitting hematocrit was less than 33%, RBC transfusion was associated with increased 30-day mortality for patients whose admitting hematocrit values were 36.1% or higher. In the analysis, these associations were present even when adjustments were made for clinical patient factors including APACHE II scores, location of myocardial infarction and presence of congestive heart failure, and treatment factors including use of reperfusion therapies, aspirin, and β-adrenergic blockade.

In the only study exclusively focusing on the perioperative period, Carson and colleagues[106] attempted to determine the effect of perioperative transfusion on 30- and 90-day postoperative mortality with a retrospective cohort study involving 8787 patients with hip fractures undergoing repair between 1983 and 1993 in 20 different U.S. hospitals. This was a large, high-risk, elderly (median age, 80.3 years) population with extensive coexisting disease and with an overall 30-day mortality rate of 4.6%. A total of 3699 patients (42%) received a perioperative transfusion within 7 days of the surgical repair. After controlling for hemoglobin concentrations, cardiovascular disease, and other risk factors for death, the results suggested that patients who had hemoglobin concentrations as low as 80 g/L and did not receive transfusion were no more likely to die than those with similar hemoglobin concentration levels who received a transfusion. With hemoglobin concentrations < 80 g/L, nearly all patients received a transfusion, which did not allow investigators to draw conclusions about the effect of transfusion at these lower hemoglobin concentration levels. However, as the authors point out, despite the large sample size, inadequate power may still explain the inability to detect a reduction in mortality related to transfusion; they estimated that the study would need to be 10 times larger to detect a 10% difference in 30-day mortality with 80% power.

More recently, Vincent and colleagues[107] completed a prospective observational cross-sectional study involving 3534 patients admitted to 146 Western European ICUs during a 2-week period in November 1999. Thirty-seven percent of these patients received RBC transfusions during their ICU admission with the overall transfusion rate increasing to 41.6% over a 28-day period. For those patients who were transfused, the mean pretransfusion hemoglobin concentration was 84 ± 13 g/L. In an effort to control for confounding created by illness severity and the need for transfusion, these investigators employed a strategy of matching transfused and nontransfused patients based on their propensity to receive a transfusion, thereby defining two well-balanced groups (516 patients in each group) to determine the influence of RBC transfusions on mortality. Using this approach, the associated risk of death was increased instead of decreased by 33% for patients who received a transfusion compared with similar patients who did not receive blood. However, as pointed out in the accompanying editorial,[108] the results may have differed if the propensity scores were derived separately for categories of pretransfusion hemoglobin concentrations (e.g., <80, 80–100, and >100 g/L) instead of hemoglobin concentrations at ICU admission. For example, if one were to consider groups of patients with pretransfusion hemoglobin concentrations less than 60 g/L, it is unlikely that the observed 33% increase in mortality would hold true, or blood transfusion would never be recommended.

Unfortunately, as evidenced by a recent systematic review, there is a paucity of clinical trials comparing restrictive and liberal transfusion policies to examine efficacy of RBC transfusion. Carson and coworkers[109] were able to identify only 10 randomized clinical trials of adequate methodological quality in which different RBC transfusion triggers were evaluated. Included were a total of 1780 surgery, trauma, and ICU patients enrolled in trials conducted over the past 40 years. The transfusion triggers evaluated in these trials varied between 70 and 100 g/L. Data on mortality or hospital length of stay were available in only six trials (Fig. 32–3). Conservative transfusion triggers were not associated with an increase in mortality; on average, mortality was one fifth lower (RR 0.80; 95% CI 0.63, 1.02) with conservative compared with liberal transfusion triggers. Likewise, cardiac morbidity and length of hospital stay did not appear to be adversely affected by the lower use of red cell transfusions. There were insufficient data on potentially relevant clinical outcomes such as stroke, thromboembolism, multiorgan failure, delirium, and infection or delayed wound healing to perform any pooled analysis. Carson and colleagues[109] stated that the data were insufficient to address the full range of risks and benefits associated with different transfusion thresholds, particularly in patients with coexisting disease. They also noted that their meta-analysis was dominated by a single trial: the

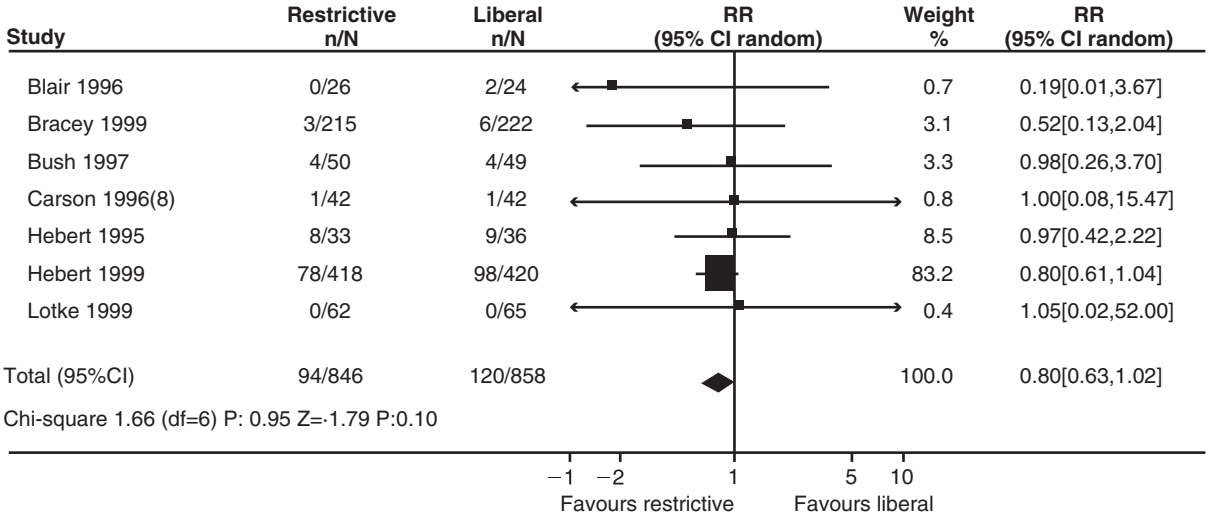

Figure 32–3 Effect of restrictive transfusion triggers on 30-day, all-cause mortality. (Adapted from Carson JL, Hill S, Carless P, et al. Transfusion triggers: a systematic review of the literature. Transfus Med Rev 2002;16:87–199.)

Transfusion Requirements in Critical Care (TRICC) trial,[110] which enrolled 838 patients and was the only individual trial identified that was adequately powered to evaluate the impact of different transfusion strategies on mortality and morbidity.

The TRICC study[110] documented an overall nonsignificant trend toward decreased 30-day mortality (18.7% vs 23.3%, $P = 0.11$) and significant decreases in mortality among patients who were less acutely ill (8.7% vs 16.1%, $P = 0.03$) in the group treated using a hemoglobin transfusion trigger of 70 g/L compared with a more liberally transfused group that received 54% more red cell transfusions. The investigators also noted that the 30-day mortality rates were significantly lower with the restrictive transfusion strategy among patients who were less acutely ill (APACHE II scores less than 20) and among patients who were less than 55 years of age (Fig. 32–4).

A number of additional questions arose from the TRICC trial. The investigators were particularly interested in the risks and benefits of anemia and transfusion in patients with cardiovascular disease and in patients attempting to wean from mechanical ventilation. In the first of these subgroup analyses,[111] 357 patients (43%) were identified with cardiovascular disease. Of these, 160 had been in the restrictive RBC transfusion group and 197 in the liberal transfusion strategy group. The two groups were fairly equally balanced with regard to baseline characteristics and concurrent therapies with a few exceptions: there was less frequent diuretic use in the restrictive group (43% vs 58%, $P<0.01$) and the use of epidural anesthetics was greater in the restrictive group (8% vs 2%, $P< 0.01$). Overall, in this subgroup analysis, there was no significant difference in mortality rate between the two treatment groups. However, there was a nonsignificant ($P=0.3$) decrease in overall survival rate in the restrictive group for patients with confirmed ischemic heart disease, severe peripheral vascular disease, or severe comorbid cardiac disease.

The subgroup analysis of patients receiving mechanical ventilation was limited to 713 (85% of the 838 patients in the TRICC trial who required invasive mechanical ventilatory support).[112] Of these, 357 had been in the restrictive RBC transfusion group and 356 in the liberal group. The mean duration of mechanical ventilation was 8.3 ± 8.1 days in the restrictive group and 8.8 ± 8.7 days in the liberal group ($P = 0.48$). Ventilator-free days were 17.5 ± 10.9 and 16.1 ± 11.4 in the restrictive and liberal RBC transfusion groups, respectively ($P = 0.09$). Eighty-two percent of the patients in the restrictive transfusion group were considered successfully weaned and extubated for at least 24 hours, compared with 78% for the liberal group ($P = 0.19$). Among the 219 patients who required mechanical ventila-

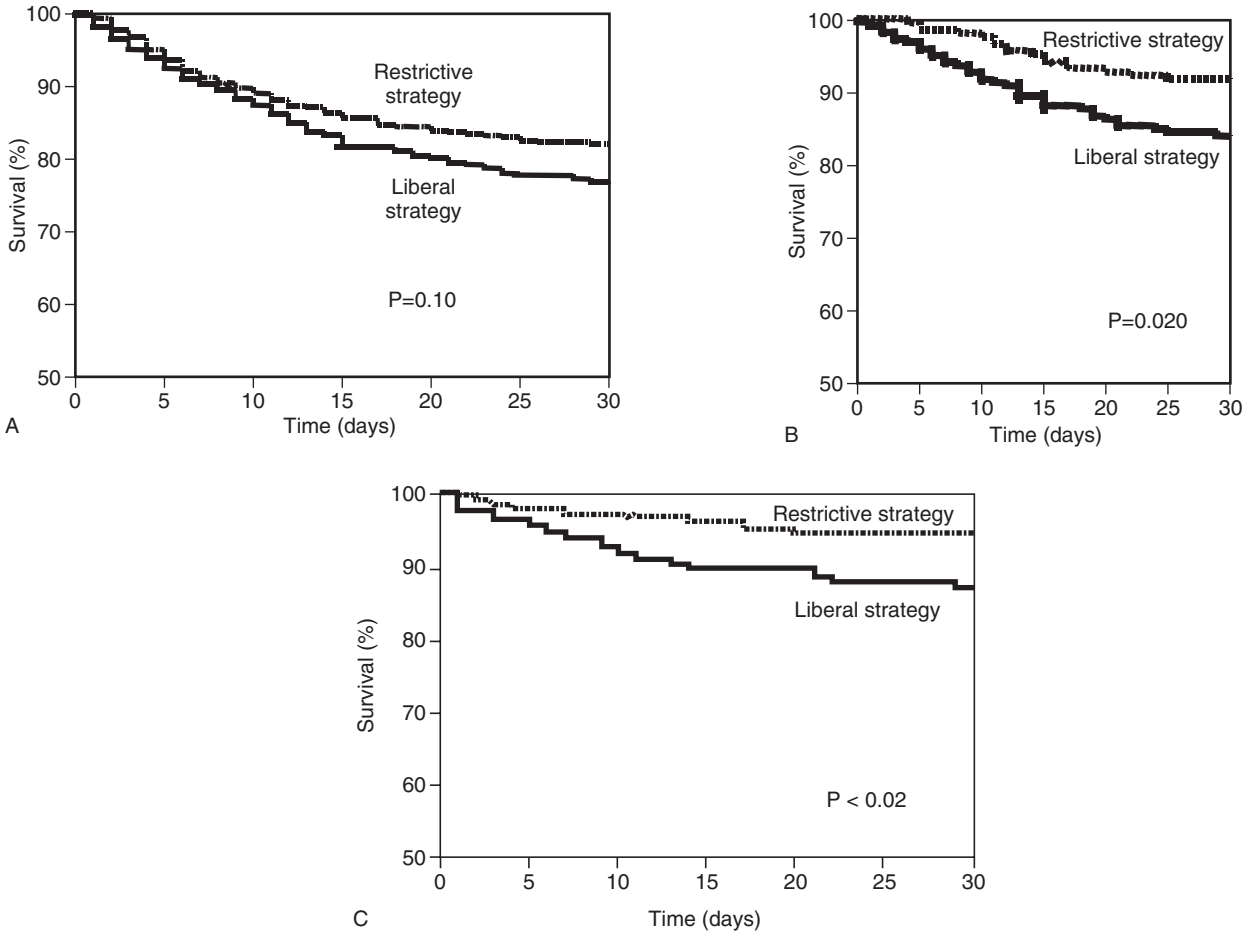

Figure 32–4 ICU survival over 30 days in study patients in the restrictive and liberal allogeneic red blood cell transfusion strategy groups. Graph **A** illustrates Kaplan-Meier survival curves for all patients in both study groups. There is a trend toward lower mortality in patients in the restrictive group (*dotted line*) compared with the liberal group (*solid line*) ($P=0.10$). In the subgroup with an APACHE II score less than 20 (graph **B**), fewer patients died in the restrictive group than in the liberal group ($P=0.02$). There were also significant differences in survival between groups in the subgroup with ages less than 55 years ($P=0.02$), as depicted in graph **C**. (Adapted from Hébert PC, Wells G, Blajchman M, et al. A multicenter, randomized, controlled clinical trial of transfusion requirements in critical care. N Engl J Med 1999;340:409–417.)

tion for more than 7 days, there were no differences in the time to successful weaning (Fig. 32–5). The independent effects of RBC transfusions and hemoglobin concentration were also examined. Each additional transfusion was associated with an increased duration of mechanical ventilation (RR = 1.10; 95% CI 1.14 to 1.06, $P < 0.01$) adjusting for the effect of age, APACHE II score, and comorbid illnesses. Hemoglobin concentrations did not influence the duration of mechanical ventilation (RR = 0.99; 95% CI 1.01 to 0.98, $P = 0.45$). Complications including pulmonary edema and ARDS were increased in patients in the liberal strategy group.

Even though a large RCT has been completed, a number of questions remain. One of the most important is why the liberal RBC transfusion strategy failed to improve 30-day mortality and rates of organ failure in critically ill patients. It is conceivable that the greater number of allogeneic RBC units in the liberal group significantly depressed host immune responses[112,113] or resulted in altered microcirculatory flow as a consequence of prolonged RBC storage times.

Following the publication of the TRICC trial, a study published by Rivers and colleagues[114] documented that early use of goal-directed care based on a mixed central venous saturation decreased mortality from 46.5% in the control group to 30.5% in the goal-directed therapy group ($P = 0.009$). As one of the many interventions in patients with early septic shock, hematocrit concentrations were increased beyond 30% if the central venous saturations fell below 70%. As a consequence of goal-directed therapy, 64% of patients compared with 18.5% of the control group received RBC transfusions ($P < 0.0001$). There are significant differences in patient populations between the study conducted by Rivers and colleagues and the TRICC trial. The early goal-directed therapy study does highlight the need to perform additional studies in subpopulations of critically ill patients.

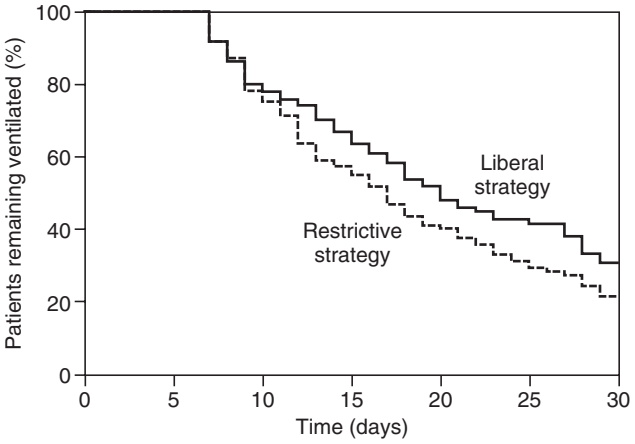

Figure 32–5 Time remaining on mechanical ventilation in the 283 patients requiring mechanical ventilation for >1 week. The time to successful weaning from mechanical ventilation is illustrated using Kaplan-Meier survival curves in patients who required mechanical ventilation for >1 week. Weaning success is defined as remaining off mechanical ventilation, once extubated, during the 30 days of observation. The hatched line refers to the restrictive group and the solid line to the liberal group. Survival curves were not statistically different when compared using a log rank test ($P = 0.08$). ALTERNATIVES TO TRANSFUSION

Numerous strategies have been explored and recommended to decrease or to eliminate the need for blood transfusions during major surgery and critical illness. Some are relatively benign, but others carry risks that must be weighed against the benefit of red cell administration. Alternatives include decreasing the use of medications that result in perioperative bleeding such as nonsteroidal anti-inflammatory drugs and acetylsalicylic acid (ASA); avoidance of unnecessary phlebotomies and the use of blood conservation strategies such as pediatric test tubes and arterial line reinfusion set-ups; medications to decrease blood loss, such as antifibrinolytic agents; and medications to increase hemoglobin production. In addition to a restrictive transfusion strategy, the two most useful approaches to decrease red cell transfusions in critically ill patients appear to be blood conservation techniques such as decreased phlebotomies and erythropoietin therapy. Other therapeutic strategies are better suited to patients undergoing high-risk surgical procedures.

Decreased red cell production is one of the causes of anemia in the critically ill. Indeed, critical illness is characterized by a blunted erythropoietin production and response.[115] This blunted response appears to result from inhibition of the erythropoietin gene by inflammatory mediators.[116,117] It has also been shown that these same inflammatory cytokines directly inhibit red cell production by the bone marrow and may produce distinct abnormalities of iron metabolism.[118,119] In patients with multiple organ failure, recombinant human erythropoietin therapy (600 units/kg) has been shown to stimulate erythropoiesis.[120] Similarly, in a small, randomized, placebo-controlled trial (160 patients), therapy with recombinant human erythropoietin resulted in an almost 50% reduction in RBC transfusions versus placebo.[121] Erythropoietin was given at a dose of 300 units/kg daily for 5 days followed by every other day therapy until ICU discharge. Despite receiving fewer RBC transfusions, patients in the recombinant human erythropoietin group had a significantly greater increase in hematocrit.

Recently, the efficacy of recombinant human erythropoietin in the critically ill was evaluated in a large, randomized, controlled trial of 1302 critically ill patients.[122] Recombinant human erythropoietin was given weekly at a dose of 40,000 units. All patients received three weekly doses, and patients who remained in the ICU on study day 21 received a fourth dose. Treatment with recombinant human erythropoietin resulted in a 10% reduction in the number of patients receiving any RBC transfusions. The authors reported a 60.4% rate of transfusions following randomization in the placebo group compared with 50.5% in the recombinant human erythropoietin group (odds ratio of 0.67 with 95% CI of 0.54 to 0.83, $P<0.0004$) and a 20% reduction in the total number of RBC units transfused in patients receiving recombinant human erythropoietin ($P< 0.001$). All clinical outcomes including mortality rates, rates of organ failure, and length of stay in ICU and the hospital were comparable between groups (all P values >0.05). Taken together, these studies[121–123] demonstrate that recombinant human erythropoietin therapy in critically ill patients results in a decrease in red cell transfusion and an increase in hemoglobin level. These observations are consistent with the hypothesis that the anemia in the critically ill is similar to the anemia of chronic disease and is characterized, at least in part, by a relative erythropoietin

deficiency.[124] However, erythropoietin therapy has yet to be shown to improve clinical outcomes.

CONCLUSION

Despite the frequent use of red cell transfusions, only one large randomized trial has examined red cell administration perioperatively and in the critical care setting. However, the TRICC trial does not provide sufficient evidence to determine optimal transfusion practice in postoperative care, in critically ill children, or in patients with myocardial infarction or acute coronary syndromes. In addition, most transfusion practice guidelines published prior to the completion of the TRICC trial[110] are now dated and need to have expert opinion informed by solid evidence in diverse clinical settings. During the next several years, randomized trials should provide additional evidence in support of bedside decision making. For example, three transfusion studies will be evaluating transfusion triggers including one in premature infants, another in critically ill children, and a third following high-risk patients who require operative repair of a hip fracture. At this time, high-quality clinical evidence is not yet available for many decisions related to red cell transfusions and alternatives such as human recombinant erythropoietin. The authors anticipate that risks and benefits of red cells and alternatives will be better elucidated in the coming years.

Chapter 33

Post-Transfusion Red Blood Cell and Platelet Survival and Kinetics: Basic Principles and Practical Aspects

Richard J. Davey • James P. AuBuchon

Investigating the fate of transfused blood cells can offer important information for the manufacturers of blood collection and storage systems, the transfusion specialists who collect and prepare the units, and patients with disorders involving reduced survival or abnormal trafficking of these cells. Tracking the recovery and survival of blood cells also allows for validation of systems' capabilities (and their improvement with innovations) as well as diagnostic procedures that can lead to therapeutic interventions for a variety of disorders.

The clinical and research applications of these techniques have led to their adoption by many medical centers. However, the technical complexity and regulatory requirements for handling radionuclides have limited their availability. Newer techniques that avoid the use of radioactive substances are under study and may eventually play a larger role in clinical applications as well as in trials of new blood collection, processing, and storage systems.

RADIONUCLIDES IN TRANSFUSION MEDICINE

Gray and Sterling[1] described the first clinically useful red cell radiolabel, chromium-51, in 1950. Fisher and colleagues[2] introduced technetium-99m as a cell label in 1967, and the importance of indium-111 was recognized after an evaluation of leukocyte radiolabels by McAfee and Thakur[3] in 1976. Other cell radiolabels have also been evaluated and used, with varying degrees of success. However, the vast majority of blood cell survival and imaging studies are performed with either chromium-51 (^{51}Cr), technetium-99m (^{99m}Tc), or indium-111 (^{111}In).

Each of the three commonly used radionuclides has advantages and disadvantages that affect its applicability in clinical and research settings. Investigators should have an understanding of fundamentals of nuclear medicine and radiation biophysics to use these materials appropriately. Desirable characteristics of a blood cell radiolabel include factors that relate to recipient safety as well as ease and reproducibility of use (Table 33–1).

The selection of an appropriate radionuclide requires familiarity with the radioactive half-life, elution characteristics, and gamma-photon energy (Table 33–2). The optimal range for detection of photoelectric events in a standard gamma-counting instrument (gamma counter) is 100 to 300 keV. The "yield" of gamma-photon emissions is the number of photons emitted per 100 radioactive decays. A high yield means that a lower radiation dose can be used to achieve adequate detection levels.

Chromium-51

^{51}Cr is a useful red cell label and also has utility as a platelet label. Advantages of this radionuclide include ease of red cell labeling, excellent red cell uptake, low toxicity, and low and stable elution rate. ^{51}Cr is produced in a reactor by neutron activation. It decays by electron capture, with a radioactive half-life of 27.7 days. The principal gamma-photon emission occurs by electron capture at 320 keV, slightly above the optimum detection range of standard gamma counters. The high energy and low yield (9.8%) of gamma-photon emissions from decay of this radionuclide necessitate a larger (typically 3-inch) NaI crystal for efficient detection in a gamma counter. Otherwise, a larger dose of this radionuclide may be necessary to achieve adequate counts.

The quite long radioactive half-life of ^{51}Cr makes it suitable for most red cell survival and recovery studies. However, this long half-life poses difficulties when multiple studies need to be performed in a short amount of time, since the overlapping survival curves make separation of the individual studies difficult. This problem can be addressed by correcting for residual radiation, by separating studies until the nuclide decays, or by using alternative radionuclides.[4]

Table 33–1 **Desirable Characteristics of Blood Cell Radiolabels**

Minimal radiation dose to the recipient
Nontoxic to the recipient
Nontoxic to the cell
Specific for the cell
No metabolism of the label by the cell
Radioactive half-life appropriate for the study
Radioactive emissions suitable for efficient detection or imaging
Minimal manipulation of the cell required
No elution of the label
No relabeling of other cells in vivo

Table 33–2 **Major Features of Radionuclides Used for Blood Cell Labeling**

	^{51}Cr	^{99m}Tc	^{111}In
Radioactivity half-life	27.7 days	6.0 hours	2.8 days
Major γ-photon emissions (yield)	320 keV (9.8%)	140 keV (90%)	173 and 247 keV (90%, 94%)
Elution rate (red cells)	1% per day	1% to 7% per hour	4% to 8% per day
Target organ*	Spleen	Total body	Spleen
Suitable for imaging?	No	Yes	Yes

*Target organ is dependent on cell type and clinical or experimental situation as well.

^{51}Cr is supplied as sodium radiochromate ($Na_2{}^{51}CrO_4$) for cell labeling purposes. Hexavalent chromate labels red cells by first binding rapidly and reversibly to the red cell membrane. After reduction to the trivalent state, the chromic ion binds more slowly and firmly to the β-globin chain of intracellular hemoglobin (and probably to other intracellular ligands as well). Labeling efficiency is about 90%. Younger red cells take up slightly more label than do older cells.

Chromium elutes from red cells in two phases. There is an early loss of 1% to 4% of the label within 24 hours, which may represent elution of a loosely bound fraction of the label.[5] Garby and Mollison[6] found that subsequent elution varies from 0.56% to 2.04% per day, similar to the 0.70% to 1.55% reported by Bentley and associates.[7] An estimated elution rate of 1% per day is satisfactory for most investigational and clinical purposes.[8] Trivalent chromium that elutes from the labeled cells is rapidly excreted in the urine and does not relabel other cells in vivo.

Moroff and colleagues[9] have described the technical steps for labeling red cells with ^{51}Cr for the evaluation of blood storage and preservation systems. The International Committee for Standardization in Hematology[10] has described a slightly different technique suitable for labeling red cells for the determination of transfusion compatibility.

Baldini and colleagues[11] first described the use of ^{51}Cr as a platelet radiolabel. The platelet-labeling efficiency of chromium-51 is low (9%) compared with its red cell labeling efficiency (90%). Therefore, it is important that platelet preparations be free of red cells before being labeled.[12] A procedure for labeling platelets with ^{51}Cr, which is more difficult than that for red cells, has been described by Snyder and colleagues.[13] Further useful refinements were developed by Heaton, Holme, and colleagues.[14,15] Unfortunately, the dose of ^{51}Cr required for imaging studies, which require a high yield of gamma-photon emissions, is typically unacceptably high for most other applications in transfusion medicine.

Technetium-99m

^{99m}Tc, which is widely employed as an imaging agent in nuclear medicine, is another useful red cell label. This metastable radionuclide is produced in a molybdenum generator as a product of molybdenum-99 decay. ^{99m}Tc decays, in turn, to ^{99}Tc, with a half-life of 6.02 hours. In doing so, ^{99m}Tc emits a gamma-photon at 140 keV, which falls within the optimal range of gamma counters. The high yield (90%) of this radionuclide is useful for external imaging. Because of the frequent use of this radionuclide in imaging procedures, many hospitals maintain a generator on site, and thus there is a readily available and inexpensive source of ^{99m}Tc for cell labeling applications.

^{99m}Tc, as pertechnetate, diffuses across the red cell membrane into the cell, where it binds to hemoglobin and other intracellular ligands with a labeling efficiency of about 90%. The short half-life of ^{99m}Tc precludes its use for long-term red cell survival studies. In fact, groups of samples must be counted rapidly, and, even with that, a correction must be made for radioactive decay that occurs during the counting procedure. However, because of its short half-life, ^{99m}Tc is useful as a red cell label when a series of survival studies must be performed for transfusion compatibility. This radionuclide is also useful for the accurate determination of red cell volume as part of red cell recovery studies (using ^{51}Cr) or in patients being investigated for possible pathologic expansion of their red cell mass (e.g., polycythemia).

This nuclide also has a high and variable rate of elution. The use of stannous compounds as intracellular reducing agents in the labeling process has permitted firmer binding of ^{99m}Tc, but elution rates of 4% per hour with considerable variation may be expected.[16,17] Heaton and colleagues[18] have described the technical steps necessary to minimize variability in labeling and elution with this nuclide. Its use as a platelet label has received little attention, however, primarily because its short half-life would prevent determination of postinfusion survival over the following 5 to 10 days, a parameter that is essential in the assessment of the effects of platelet collection and storage conditions.

Indium-111

^{111}In can be used as a label for red cells, platelets, and leukocytes. It is prepared in a cyclotron by proton bombardment of a cadmium target. It has two major gamma-photon emissions—173 keV (90.5% yield) and 247 keV (94% yield)—which are excellent for counting in a gamma counter and for external imaging. The radioactive half-life of the nuclide is 2.83 days, making it appropriate for leukocyte imaging studies that extend over several days.

^{111}In must be complexed with a lipophilic chelating agent if it is to traverse cell membranes and label intracellular proteins. Although several lipophilic chelates have been studied, 8-hydroxyquinoline (oxine) is the only agent currently licensed for this purpose in the United States. Technical procedures have been published for labeling red cells,[19] platelets,[13] and leukocytes[20] with ^{111}In.

Although ^{111}In is a nonselective label, it is preferentially taken up by platelets. Reduced uptake is observed by leukocytes, and still less by red cells.[21] Cell preparations therefore must be free of extraneous elements before being labeled. Like ^{99m}Tc,^{111}In has a high and variable rate of elution from red cells. AuBuchon and Brightman[19] have shown that 8% to 10% of the label elutes within 24 to 48 hours, with a 4% per

day loss after that time. This problem with elution renders ^{111}In unsuitable for red cell studies without a specific correction factor,[22] but ^{111}In is useful for determining red cell volume when precision is not critical.

BLOOD CELL LIFE SPAN AND SURVIVAL STUDIES

Red Cells

The red cell life span (110 to 120 days) was first approximated by differential absorption techniques[23] and subsequently confirmed by radioisotopic labeling studies using cohort (marrow) labels[24] and random (peripheral blood) labels.[6] When chromium-51 is used as the label, the time at which the recovered counts are 50% of the originally injected counts is the T_{50}Cr, normally 31 ± 6 days. Correction for elution will yield the true red cell life span. The T_{50}Cr is also useful for evaluating the extent of hemolysis in chronic hemolytic anemia. Modest reductions in the T_{50}Cr can indicate a substantial increase in the rate of red cell destruction.[25]

Red cell life span studies also have been conducted to assess the therapeutic benefit of transfused units that are enriched in young red cells ("neocytes"). The transfusion of such units has the theoretical benefit of reducing the iron burden in patients who undergo frequent transfusions by increasing the number of long-lived red cells in the circulation.[26] Chromium-51 life span studies have demonstrated that neocytes survive 30% to 60% longer in the circulation than do red cells derived from standard red cell units.[27,28] However, because neocyte units contain only about half the hemoglobin of standard units, their use results in only a modest reduction in transfusion requirements.[29,30] Additionally, since they are costly to prepare, neocyte transfusions have not achieved wide clinical acceptance.

In contrast to long-term life span studies, short-term red cell survival studies are useful in identifying patterns of immune red cell destruction. These studies are clinically important when standard pretransfusion serologic testing cannot clearly identify or characterize red cell alloantibodies or autoantibodies in a transfusion recipient. The various factors that contribute to immune red cell destruction have been discussed in detail elsewhere.[31–33] Of primary importance are the immunoglobulin class and subclass of the recipient red cell alloantibody[34] and the extent to which that antibody activates complement.[35,36]

Four characteristic survival patterns can be recognized in a 24-hour red cell survival study conducted to determine transfusion compatibility (Fig. 33–1). They are (1) normal survival, (2) extravascular destruction characterized by a "two-component" survival curve, (3) extravascular destruction characterized by a "single exponential" survival curve, and (4) intravascular destruction.

Normal Survival

The normal range for recovery of fresh, compatible red cells is ≥97% at 60 minutes and 95% to 100% at 24 hours.

Extravascular Destruction Characterized by a "Two-Component" Survival Curve

Most immunoglobulin M (IgM) red cell alloantibodies and some IgG alloantibodies (e.g., anti-Jk^a) can activate complement. IgM antibodies directly activate complement, with 20 to 40 IgM molecules per red cell being required to initiate red cell clearance. IgG antibodies can activate complement if two or more molecules are physically adjacent on the red cell membrane[37]; thus, many more IgG molecules are required for complement activation to occur. In most cases, the kinetics of complement activation result in generation of the membrane-bound C3b fragment but not the final C5b-C9 "membrane attack" complex. Plasma factor I, with plasma factor H as a cofactor, cleaves C3b to C3bi. Red cell–bound C3b and C3bi adhere to the complement receptors CR1 and CR3 on reticuloendothelial system (RES) macrophages in the liver and spleen. These red cells may thus be removed from the circulation by either antibody-dependent cell-mediated cytotoxicity or complete phagocytosis, or they may sustain membrane damage through partial phagocytosis. Alternatively, C3bi may be degraded before red cell damage occurs.[38,39]

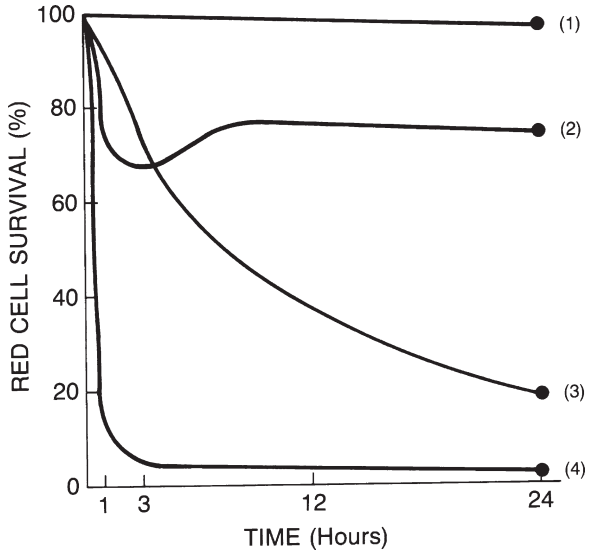

Figure 33–1 Red cell survival patterns representing different mechanisms of immune red cell destruction. (1), Normal survival; (2), two-component curve with partial complement activation to C3b→C3d,g; (3), single exponential curve characteristic of IgG non-complement-activating antibodies; (4), complete complement activation to C5b-C9 complex with intravascular hemolysis.

Plasma factors I and H further cleave C3bi to C3c, which detaches from the cell, and C3d,g, which remains attached to the cell membrane. Because C3d,g binds weakly to CR3 receptors, most red cells coated with C3d,g detach from RES macrophages and survive relatively normally.[40] The inactive C3d,g fragments may protect the red cell from further complement-mediated damage by occupying complement-binding sites. A "two-component" recovery curve, therefore, represents the early loss of C3b-coated red cells and more normal survival of those cells on whose membranes C3b has degraded to C3d,g. A "two-component" survival curve with more than 70% recovery at 24 hours indicates that the patient can safely receive larger quantities of similar red cells with little risk of rapid immune hemolysis.

Extravascular Destruction Characterized by a "Single Exponential" Survival Curve

Many IgG red cell alloantibodies (e.g., Rh antibodies) do not activate complement. Instead, there is progressive removal of sensitized red cells with a survival curve described by a single exponential. Factors such as the concentration and IgG

subclass of the antibody determine the rate of removal of the cells. The efficiency of the four IgG subclasses in binding Fc receptors on RES macrophages is $IgG_3 > IgG_1 > IgG_2 > IgG_4$. IgG1 is present in higher titer than the other subclasses and is most often involved in IgG-mediated red cell destruction.[34] Red cell survival studies that demonstrate an IgG-mediated "single exponential" pattern of cell destruction indicate that the transfusion of similar cells may result in a delayed hemolytic transfusion reaction.

Intravascular Destruction

IgM antibodies that are efficient activators of complement, such as anti-A and anti-B, can drive the kinetics of the reaction to the formation of the terminal C5b-C9 "membrane attack" complex. Insertion of this complex into the red cell membrane results in loss of membrane integrity and osmotic lysis of the cell. Transfused cells that generate complement activation of this magnitude are usually hemolyzed within minutes.

Synergistic Effect of Complement and IgG

Complement and IgG appear to act synergistically in promoting red cell opsonization. Studies have demonstrated that the addition of complement to red cells sensitized with IgG alone will enhance phagocytosis.[41,42] A hybrid red cell survival curve may occur when both IgM and IgG antibodies are active. There is a rapid loss of a minor population of the cells from IgM-mediated complement activation, and a slower phase of cell destruction mediated primarily by the IgG antibody.

Platelets

Most studies of platelet life span and kinetics have been performed with chromium-51 and/or indium-111 using labeling procedures defined by the ICSH[43] and Heaton and Holme.[15] The low labeling efficiency, long half-life, and poor imaging characteristics of ^{51}Cr have led to preferential use of ^{111}In when a single platelet label is required.[44] However, serial studies in a subject using a single label may not be possible, since platelet kinetics vary over time. By using both chromium and indium labels for simultaneous infusion, a reduction in this variability is seen, and a more accurate estimation of the difference between platelets stored in a standard (or licensed) system and those in a test system can be achieved.[45] Using "dual-label" approaches in a protocol can allow simultaneous storage and labeling of test and control platelets (e.g., in different bag types). This technique has also been used to create novel approaches to the timing of collections, such as in a study where whole blood–derived platelets stored for 5 days were compared with those stored for 7 days. The test (7-day) platelets were derived from a unit collected on day 0 (with reinfusion of the red cells), and the control (5-day) platelets were derived from a collection 2 days later. Platelets from both study arms were labeled and infused simultaneously.[46]

Standard technical methods for preparation of radiolabeled platelets have been published by the ICSH and others.[13,15,47] The major drawback of ^{111}In-oxine is its high affinity for red cells, leukocytes, and plasma proteins, primarily transferrin. The washing and centrifugation steps necessary to prepare a "clean" platelet preparation cause a substantial loss of platelets (≈40%) and a "collection injury" that can distort test results if not performed carefully. Other compounds that form lipophilic complexes with ^{111}In, notably, acetylacetone,[48] tropolone,[49] and 2-mercaptopyridine-N-oxide (merc),[50] have been extensively studied as possible alternative agents to overcome this problem. Tropolone is widely used in Europe, but oxine remains the only licensed agent in the United States.

Heaton and colleagues contributed to the advancement of platelet labeling accuracy by developing a technique for determining the amount of radionuclide that elutes from platelets shortly after labeling and infusion.[15] With this "elution correction," the recovery curves for platelets labeled with ^{111}In are coincident with those labeled with ^{51}Cr. This procedure is the basis of the standard platelet radiolabeling protocol adopted by the Biomedical Excellence for Safer Transfusion (BEST) Collaborative.[51]

There are four methods for the calculation of platelet life span—linear, exponential, weighted mean, and γ-function (multiple hit)—each of which yields slightly different results. The γ-function analysis is the recommended method[13,43] and the most frequently used, but investigators often report their results using one or more additional statistical methods. An easy-to-use computer program that models platelet survival by a variety of techniques performs these calculations in a standardized, validated manner.[52,53] These calculations can also be performed on statistical analysis software to achieve the same results. The area under the survival curve has also been reported, but some believe this measure places an inordinate weight on the survival parameter.[54]

Because no radioactive tracer selectively labels newly formed platelets, cohort studies have not been practical to measure platelet production. Instead, the kinetics of normal platelet production has been measured indirectly by determining the turnover rate of circulating platelets (platelet count divided by platelet survival corrected for recovery). Estimates of daily platelet production in the steady state using this method have ranged from 35,000–66,000/μL of blood.[55] The life span of human platelets ranges between 8 and 12 days; Harker and Finch[56] found it to be 9.5 ± 0.6 days. Senescent platelets are removed from the circulation by RES macrophages in the liver and spleen and, to a lesser extent, by bone marrow and lungs.[57,58]

There is also evidence of a fixed platelet requirement necessary to maintain vascular integrity. Hanson and Slichter[59] have proposed that 82% of platelet turnover in normal persons is due to senescence, and 18% (≈7100 platelets/μL/day) is due to the fixed requirement. The fixed requirement becomes an increasingly large component of platelet removal as thrombocytopenia from bone marrow hypoplasia worsens. Thus, platelet life span correlates directly with the platelet count; an accelerated reduction in life span is noted as platelet counts decrease below 50,000/μL. The shortened platelet life span observed in thrombocytopenic patients, therefore, does not necessarily indicate an increased platelet destruction rate.

Patients with increased peripheral platelet destruction, such as those with idiopathic thrombocytopenic purpura,[60] have platelet life spans that are shorter than predicted by Hanson and Slichter's model.[59] Thus, platelet life span studies using ^{111}In are useful in discriminating between thrombocytopenia caused by decreased platelet production and that caused by increased platelet destruction (Fig. 33–2). Platelet life span studies are not generally useful in the alloimmunized patient, however. Post-transfusion platelet counts usually provide the clinician with the information necessary for the management of these patients.

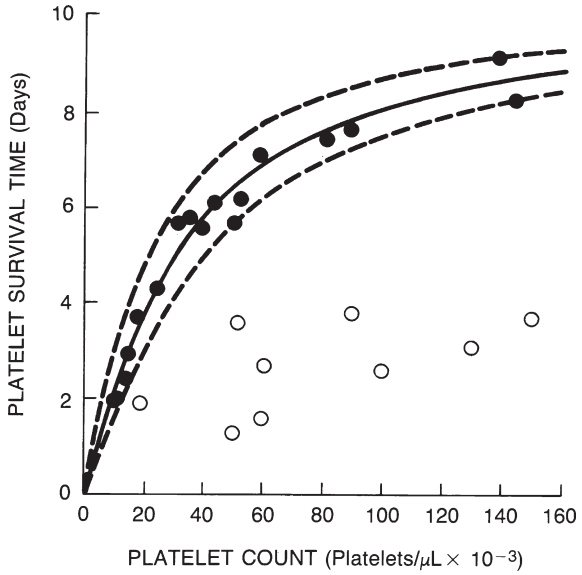

Figure 33–2 Relationship between the survival of ^{111}In-labeled autologous platelets and the circulating platelet count. *Solid circles* identify patients with impaired platelet production (hypoplasia; $n = 17$). *Open circles* identify patients with increased peripheral platelet destruction (ITP; $n = 9$). *Solid line* is best fit to data from the hypoplastic patient group. Platelet survival could be predicted by platelet count in the hypoplastic patient. The "fixed requirement" is increasingly apparent in this group at platelet counts below 50,000/μL. (Adapted from Tomer A, Harker LA. Megakaryocytopoiesis and platelet kinetics. In Rossi EC, Simon TL, Moss GS [eds]. Principles of Transfusion Medicine. Baltimore, Williams & Wilkins, 1991, p 175.)

Leukocytes

Although granulocytes, lymphocytes, and monocytes derive from a common pluripotent stem cell, they have widely variant functions and kinetics. Radionuclides have permitted the study of the normal kinetics of these various leukocyte classes.[61] ^{111}In-oxine is now the nuclide of choice for leukocyte radiolabeling. Because labeling with ^{111}In-oxine is nonselective, the leukocytes of interest must be separated from other cells and plasma before being labeled.[62]

Granulocytes

Studies done with granulocytes labeled with diisopropylfluorophosphate demonstrated that the circulating cells had a half-life of 3.8 to 6.7 hours. About half of the injected cells were recoverable in the circulation, with the remainder constituting a "marginating pool" of cells.[63,64] More recent studies done with ^{111}In-labeled granulocytes have shown a mean recovery of 30% of the labeled cells and a mean circulating half-life of 5.0 hours.[65] Imaging studies have shown that labeled and transfused granulocytes transiently sequester in the lungs. The extent and duration of the pulmonary sequestration appear to be more severe when the labeled cells are suspended in saline rather than plasma.[66] Alloimmunized patients demonstrate a more prolonged and intense pulmonary sequestration phase than do normal subjects.[67] In addition, HLA (human leukocyte antigen)– and granulocyte-specific antibodies appear to reduce the intravascular half-life of transfused granulocytes[68] and to impair their ability to migrate to a site of active infection.[69]

Lymphocytes

The extreme radiosensitivity of lymphocytes has hampered the conduct of kinetic and imaging studies. Autologous lymphocytes labeled with a low dose of ^{111}In (>20 μCi/10^8 cells) move rapidly from the circulation and sequester in the lung, liver, and spleen. A more gradual accumulation of radiolabel in the lymph nodes follows.[70] These findings are consistent with studies indicating that most lymphocytes are part of a large recirculating pool consisting of long-lived, nondividing cells.[71,72] Lymphocytes in this pool migrate from the circulation to the various lymphoid tissues, where they have opportunity to interact with foreign antigen. The migration patterns are not random but are modified by the lymphocyte class and immunologic history of the cell. T cells preferentially migrate to lymph nodes, whereas B cells tend to migrate to mucosal lymphoid tissue.[72] Lymphocytes collected from a specific type of lymphoid tissue (e.g., gut mucosa) move to that tissue because of "homing receptors" expressed on the cell after specific antigenic stimulation.[73]

Activated Mononuclear Cells

Kinetic studies of human monocytes have been limited because of the difficulty of obtaining a homogeneous collection of cells and because of technical problems with cell activation and clumping during preparation. However, monocytes prepared by leukapheresis, density gradient separation, and countercurrent elutriation have been activated with interferon-γ and infused intraperitoneally in patients with peritoneal spread of colorectal cancer.[74] In two patients, ^{111}In-labeled cells remained in the peritoneal cavity for up to 5 days after infusion, supporting the observation of clinical improvement in a larger group of patients treated with unlabeled activated monocytes.

A subpopulation of peripheral blood lymphocytes activated with the cytokine interleukin-2 has been found to exhibit antitumor activity. These lymphokine-activated killer cells presumably migrate to tumor sites, but cell trafficking and imaging studies have been inconclusive.[75] Lymphocytes directly harvested from tumor sites (tumor-infiltrating lymphocytes), however, have been shown to localize at tumor sites and persist in the circulation after activation.[76]

PROTOCOLS TO EVALUATE COMPONENT COLLECTION, PROCESSING, AND STORAGE SYSTEMS

The two critical advances that led to modern blood preservation techniques were the introduction of acid-citrate-dextrose in 1943[77] and the development of plastic blood containers in the early 1950s. Now, blood components are stored in various anticoagulant-preservative or additive solutions, in plastic containers with differing characteristics, and at nonphysiologic temperatures for extended periods. The advent of pathogen inactivation systems offers great potential for improving transfusion safety but at potential risk of injury to the cells during the process. For this reason, the safety and efficacy of new or modified storage conditions must be determined by both in vitro and in vivo evaluation of cell function and viability.

A variety of biochemical, hematologic, and functional parameters are often measured across the storage period in

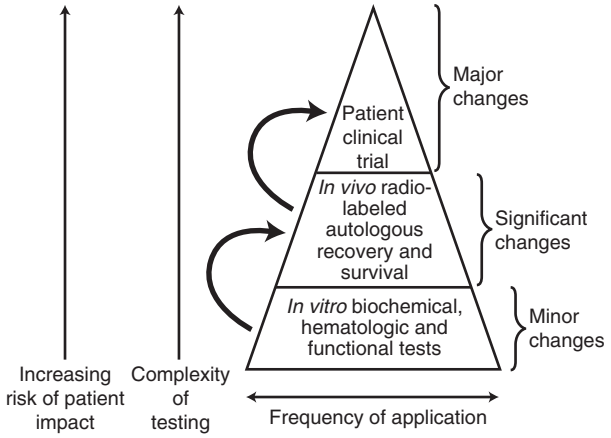

Figure 33–3 Scheme for progressive analysis of new blood component. A representation of the progressive analysis of a new blood component illustrating (1) the stepwise nature of investigation (beginning with in vitro testing and culminating with clinical trials) and (2) application of different degrees of scrutiny based on the extent to which the new component differed from previously investigated ones. Note that major changes would involve more extensive investigation using more complex testing techniques in response to an increase in the risk of (adverse) patient impact. More commonly encountered, simpler changes to a collection or storage system would more likely require only in vitro testing. Successful testing (indicative of safety and efficacy) at one level of the pyramid would be used to justify moving to the next "higher" level of testing, were that required. (Adapted from a presentation by Dr. Jaro Vostal.[79] Reprinted with permission from AuBuchon JP. Radioisotopic reflections. Transfusion 2005;45:28S–32S.)

an attempt to predict the in vivo outcome after transfusion. It is known, for example, that retention of at least half the original adenosine triphosphate (ATP) concentration in red cells is necessary for adequate recovery and that a $pH_{22°C} \geq 6.2$ for platelets is required in order to retain viability. Beyond these notable exceptions, however, few strong correlations between any in vitro parameters and life span in circulation after storage have been identified.[78] Therefore, documentation of the in vivo recovery (and, for platelets, survival) remains necessary whenever a substantial change in collection, processing, or storage is being proposed. The FDA has described the role of in vitro and in vivo testing as part of a "pyramid" of trials leading to approval of a new device or protocol[79] (Fig. 33–3). Radiolabeled kinetic studies thus remain a critical feature of this approach, which allows definitive documentation in a relevant (human) system and ensures that patients are likely to receive sufficient therapeutic benefit from the component under study.

Red Cells

The 24-hour post-transfusion recovery of red cells stored under experimental conditions is the standard measure of acceptability used in the United States. The FDA requires that a mean of 75% or more of the transfused red cells be recovered 24 hours after infusion. The lower bound of the 95% confidence interval is expected to be at least 70%. Although these criteria have never been encoded in federal regulations or statutes, they have become the accepted measures to obtain licensure. Long-term survival is not a parameter usually measured, since, at least before the advent of pathogen inactivation technologies, postinfusion longevity was assumed to be normal providing the red cell showed acceptable 24-hour survival.[80] Other measures, such as poststorage ATP and supernatant hemoglobin levels, contribute to the assessment of storage condition acceptability. Red cell recovery data have been important in studies evaluating the effect of gamma-irradiation,[81,82] blood bag plasticizing agents,[83] and prestorage leukocyte reduction[84] on stored red cells.

The technique for performing post-transfusion recovery studies to assess new storage conditions differs in important ways from red cell recovery studies to assess transfusion compatibility. As noted in Table 33–3, autologous red cells are chosen for storage studies, thereby avoiding the risks of transmissible disease and transfusion reactions inherent in allogeneic transfusions. The shape of the recovery curve is most important in transfusion compatibility studies. However, the recovery percentage at 24 hours is of prime importance for studies evaluating storage systems.

Because an accurate determination of 24-hour recovery is necessary, the method of establishing the zero-time point (100% recovery) is of critical importance. A direct measurement of the zero-time recovery value is not possible, however, because an infused blood sample is not completely mixed until approximately 3 minutes after transfusion in a normal person.[85] Senescent infused cells and cells damaged during storage are removed from the circulation by the spleen, with loss of these cells beginning immediately after infusion. By 3 minutes, a significant loss of the infused cells may have occurred that is not detected if the 3-minute sample is regarded as representing 100% survival. In this case, the radioactive counts in the 3-minute sample would be

Table 33–3 **Features of Red Cell Survival Studies to Evaluate Transfusion Compatibility and Red Cell Storage Systems**

Purpose of Evaluation	Features of Study
Transfusion compatibility	Allogeneic cells—chosen by specific phenotype Fresh cells (<5 days old)—avoid storage lesion Small volume infused (1 to 3 mL)—reduces risk of transfusion reaction Zero-time (100% recovery) point determined after mixing is complete (3–5 minutes) Interpretation—shape of 24-hour survival curve predictive of clinical significance of recipient antibody
Red cell storage	Autologous cells—avoid risks of allogeneic transfusion Larger volume infused (10–15 mL)—easy to manipulate and smaller radiation dose per cell Zero-time (100% recovery) point determined by independent red cell mass study (double-label method) or back-extrapolation (single-label method) Interpretation—precise determination of recovery at 24 hours (>75% mean recovery required)

falsely low and the 24-hour recovery value falsely elevated. Two methods for calculating the zero-time recovery value are useful in red cell storage evaluation studies: the single-label and the double-label techniques.

Single-Label Technique with Back-Extrapolation

The in vivo destruction of damaged stored red cells begins immediately and can be assumed to continue at a first-order rate. If so, the extrapolation of the logarithm of the post-transfusion counts to the *y*-intercept should yield an accurate determination of the zero-time counts, or the 100% recovery point. Beutler and West[86] compared the red cell mass calculated by the extrapolation method with the red cell mass determined independently using red cells labeled with ^{99m}Tc.[86] They found that extrapolation using fresh red cells yielded red cell mass values that were almost identical to those determined independently. When red cells had been stored for 35 to 49 days, however, there was a consistent overestimation of red cell mass (0.6% to 3.6%) by the extrapolation method, suggesting that the kinetics of the early removal of stored red cells is not described solely by a first-order rate equation (Fig. 33–4).

The removal of damaged and senescent red cells occurs within 15 to 20 minutes of transfusion. Moroff and colleagues[9] have shown that there is a break in the recovery curve at 15 minutes, with red cells persisting after that time having more normal survival. The recovery points used for extrapolation to the *y*-intercept, therefore, should be those obtained after 5 minutes, to ensure complete mixing, and before 15 minutes, to avoid the break in the recovery curve. Moroff and colleagues[9] and others[32,87] have described in detail the technique and interpretation of red cell recoveries using the single-label method.

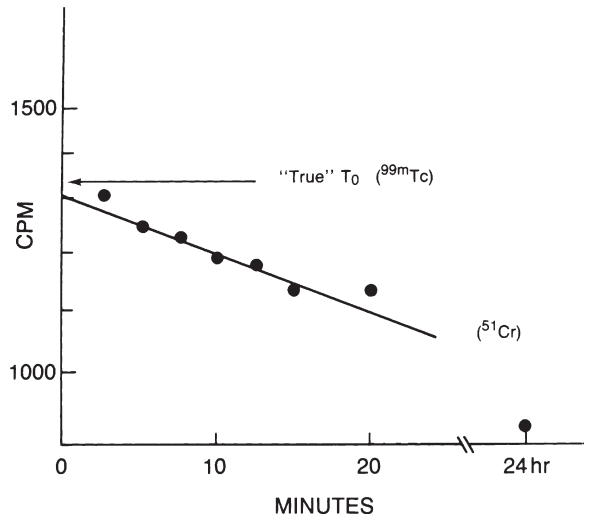

Figure 33–4 Two methods to calculate the counts per minute (CPM) at zero-time (T_0) for determination of red cell mass. With the single-label technique *(solid dots)*, the ^{51}Cr-labeled test cells are infused and samples are obtained at 5, 7.5, 10, 12.5, and 15 minutes after infusion. A regression line is plotted, and the y-intercept (T_0) is determined. In the double-label technique, an independent, or "true," measure of T_0 is determined *(arrow)* with fresh autologous red cells labeled with ^{99m}Tc. The single-label regression technique underestimates CPM at T_0 and, therefore, overestimates 24-hour red cell recovery, with the error increasing as red cell storage time increases. (Adapted from Beutler E, West C. Measurement of the viability of stored red cells by the single-isotope technique using ^{51}Cr. Transfusion 1984;24:100.)

Double-Label Technique with Direct Measurement of the Red Cell Mass

An accurate determination of the recipient's red cell mass provides the correct volume of dilution for the experimental red cell sample. Simultaneous infusion of fresh, autologous red cells labeled with ^{99m}Tc and stored experimental red cells labeled with ^{51}Cr permits this determination. The fresh, autologous red cells labeled with ^{99m}Tc are not removed by the spleen. Early samples, obtained after complete mixing, can be used to determine an accurate red cell mass. Subsequent samples counted for the ^{51}Cr-labeled experimental cells can be compared with zero-time ^{51}Cr determination calculated from the counts of ^{51}Cr injected and the volume of dilution or red cell mass. The major gamma-photon emissions of ^{51}Cr and ^{99m}Tc permit simultaneous counting of these radionuclides. Alternatively, the red cell mass can be determined and the ^{99m}Tc be allowed to decay before the samples are counted for ^{51}Cr.

The double-label method is accurate when properly performed. However, it is technically more difficult than the single-label method, especially in the preparation of the ^{99m}Tc-labeled cells. Heaton and colleagues, who have described the double-label technique in detail, have stressed the importance of keeping the ^{99m}Tc-labeled sample at 4° C to retard elution of the label before infusion.[18] Nevertheless, the most appropriate means of determining blood volume at the time of a radiolabeled red cell recovery infusion remains open for debate. Since the general adoption of the double-label approach 20 years ago, the ^{99m}Tc double-label approach has been found to differ slightly but consistently from the ^{51}Cr single-label approach even when good red cell recovery is noted.[88] Single-label recoveries appear to be about 1% to 2% *lower* than double-label calculation techniques. The single-label technique is simpler, cheaper, and exposes subjects to less radioactivity, but the double-label technique affords an independent opportunity to confirm the blood volume should an unexpected problem befall the interpretation of the ^{51}Cr recovery curve.

Platelets

The evaluation of platelet storage and preservation has been complex and challenging. Investigators generally conduct studies using normal volunteer subjects, with each subject serving as his or her own control. Data are usually reported as platelet recovery at 1 to 3 hours and as platelet survival or half-life over several days. Both ^{51}Cr and ^{111}In are suitable radiolabels for platelet storage studies,[89–91] and double labeling with ^{111}In and ^{51}Cr is well established.[15,92] Platelet recovery and survival studies have been critical to the development of plastics that permit 5-day platelet storage,[93,94] to the identification of the optimal temperature for platelet storage,[95,96] to the determination of proper agitation of the platelet concentrates,[97] and to the comparison of manual platelet preparation with automated plateletpheresis techniques.[98] These studies have traditionally compared a new approach for collection, processing, or storage with an established one.

Unlike red cell studies, however, there is no established criterion of acceptable performance. The test system has usually been accepted if (1) the statistical analysis failed to show a statistical difference in comparison to an established (i.e., previously licensed) method, or (2) a difference was documented but it was not regarded as being *clinically* significant.

There are obvious limitations to this approach. Trials involving radionuclide injections in normal subjects are usually small ($N < 25$) to limit exposure to radioactivity and costs and, as a result, have limited power to detect real differences that may be present. When differences are detected, the definition of what is a clinically relevant difference has remained subjective. Repetitive comparisons—as today's "test" system becomes tomorrow's "control system"—may lead inevitably to a "creeping inferiority"[54] of platelet components that could negatively affect patient care. Arbitrary standards for recovery and survival of platelets could be developed, but one would still need to validate a laboratory's techniques.

An alternative standard based on fresh platelets has been proposed by Murphy.[54] The control arm for trials would always be the infusion of fresh (autologous) platelets. Test platelets would be expected to demonstrate at least two thirds the recovery and half the survival of the standard-setting fresh platelets. The actual protocol design for this kind of trial has received much discussion.[99] Currently utilized apheresis platelets meet the criterion proposed by Murphy,[100] as do both apheresis[101] and whole blood–derived platelets[46] stored for 7 days. This approach needs to be tested through additional studies, but it has promise to permit clear regulatory decisions as well as to increase the assurance of platelet transfusion efficacy for patients.

Granulocytes

Granulocytes collected by a variety of techniques and labeled with ^{111}In migrate to sites of infection. They demonstrate a similar kinetic pattern in the lung, liver, and spleen.[102,103] McCullough and colleagues[104] demonstrated that post-transfusion granulocyte migration to skin window chambers was impaired when the cells were stored for 8 hours at 1° C to 6° C or for 24 hours at 22° C. Granulocytes stored for 8 hours at 22° C, however, migrated as well as unstored controls.

IMAGING AND OTHER DIAGNOSTIC APPLICATIONS

Blood cells labeled with appropriately chosen radionuclides migrate to sites of disease where they can be detected by collimated scintillation cameras. These devices consist of a sodium iodide crystal that interacts with collimated gamma-photons emitted from the source. Visible light is produced, which is recorded by photomultiplier tubes and converted into an image by means of a dedicated computer interfaced with the camera. The imaging of radiolabeled granulocytes is especially useful in clinical medicine, and the imaging of platelets and red cells can also be important in selected situations.

Red Cells

The diagnostic uses of imaged radiolabeled red cells include the localization and sizing of the spleen or accessory spleen, blood pool scanning, and the detection of gastrointestinal bleeding and vascular anomalies such as hemangiomas. Colloids such as rhenium sulfur labeled with ^{99m}Tc are often used to determine spleen size and location. Radiolabeled colloids also image the liver. On occasion, it is desirable to image the spleen alone, especially when an enlarged liver interferes with splenic images or when an accessory spleen is suspected. For these needs, red cells damaged by heat and labeled with ^{99m}Tc localize in the spleen without significant hepatic uptake.[105]

The blood pool can be imaged, and related red cell kinetics determined, with red cells labeled with ^{111}In. Quantitative sequential counting and imaging are possible, focusing on a selected target organ such as the spleen. This procedure can determine the rate of splenic sequestration when increased peripheral destruction of red cells is suspected (Fig. 33–5). However, this technique is infrequently utilized.

A common use of radionuclide labeling of autologous red cells is for the determination of red cell mass (or volume) in the diagnosis of polycythemic states. ^{99m}Tc provides the requisite information with a relatively small dose of radioactivity. Samples need only be acquired over the first 15 to 30 minutes after reinfusion.

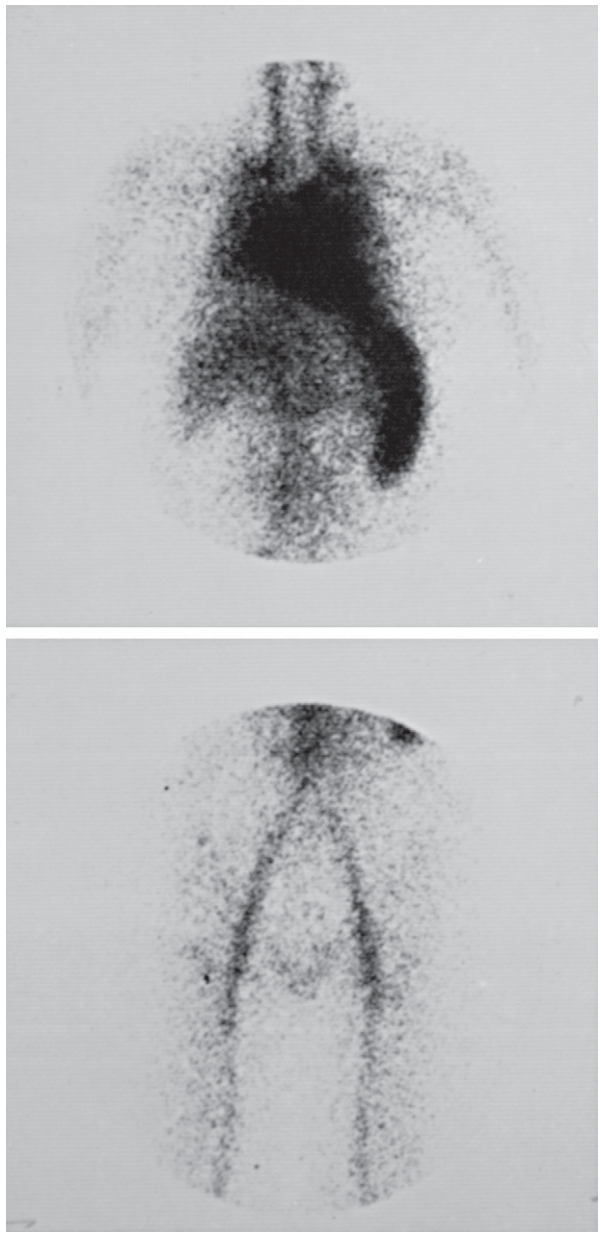

Figure 33–5 ^{111}In-labeled red cell blood pool scan. The heart, great vessels, liver, and enlarged spleen are clearly imaged. Differential counting over selected organs can identify sites of red cell sequestration.

Platelets

Platelets labeled with ^{111}In can be detected and imaged at the sites of their deposition, such as in intravascular thrombi. An actively forming clot incorporates platelets. Therefore, radiolabeled platelets are useful in identifying areas of *new* thrombus formation but do not label older thrombi. A venogram is often used to confirm a positive platelet scan. However, platelet scanning is reliable as a single diagnostic test and is especially useful in patients who are allergic to intravenous contrast material. Applications for the use of radiolabeled platelets include detection of venous, arterial, and intraventricular thrombi, pulmonary emboli, and aneurysms.[106,107] In addition, this technique can aid in the evaluation of the status of renal transplants[108] and arterial grafts.[109] If a suspicious area is identified on the early scans, the site is followed for several days to note whether the area persists or increases in activity as blood pool activity decreases. In a prospective study of gynecologic patients at high risk, 29% demonstrated increased platelet deposition in the major veins or lungs that were presumptive sites of thrombus formation.[110]

Granulocytes

^{111}In-labeled granulocytes are used to identify areas of infection and inflammation, such as suspected abscesses[111] or osteomyelitis,[112] or to evaluate a fever of unknown origin.[113] ^{111}In is usually preferred over gallium-67 citrate, an agent that is incorporated into phagocytic cells in vivo, because of the former's superior image quality and the absence of accumulation of the tracer in the gastrointestinal and urinary systems.[114] The technique for preparing granulocytes for imaging studies has been described by Loken and colleagues.[20] For most imaging studies in adults, 1 to 3×10^8 granulocytes are labeled with 400 to 500 μCi of indium-111. Autologous cells are used whenever possible, but allogeneic granulocytes must be used for patients with granulocytopenia or functional granulocyte defects.

FUTURE DIRECTIONS AND NEW APPLICATIONS

The necessity to identify and label formed hematopoietic blood elements, and to follow their in vivo kinetic and localization patterns, will continue as specialized cells designed for targeted clinical applications are developed. For example, mononuclear cells modified for adoptive immunotherapy of cancer is an exciting area in which knowledge of in vivo cell behavior after reinfusion is incomplete.[115–117]

Direct in vivo labeling of cells avoids damage to cells that may occur during in vitro labeling procedures. Coller[118] has described a monoclonal antiplatelet antibody that binds to platelet glycoprotein IIb-IIIa in vivo. This monoclonal antibody can be radiolabeled for localization of thrombi and other vascular lesions.

Improvements in the currently used radionuclides will enhance their clinical utility. Specifically, new chelates of ^{111}In and modifications in labeling procedure using ^{99m}Tc could reduce the high rates of elution that complicate their use. Stannous glucoheptonate, for example, results in a more stable ^{99m}Tc red cell label than can be achieved with the standard method using stannous citrate.

Nonradioactive isotopes avoid the delivery of an absorbed radiation dose to the recipient, and a variety have been developed. ^{50}Cr binds easily to red cells but is cumbersome to produce and detect. Heaton and colleagues[119,120] have demonstrated, however, that ^{52}Cr can be detected using advanced atomic absorption spectrophotometric techniques and is comparable to ^{51}Cr in red cell volume and post-transfusion survival studies. The scrupulous cleanliness and analytic technology required, however, put this technique beyond all but the most determined investigators. Red cells also can be labeled with biotin and then detected with a fluorescent or radioactive tag attached to streptavidin in ex vivo analysis. This technique has been used to determine blood volume and to track the survival of transfused red cells. The results correlate closely with ^{51}Cr-labeled red cells, but the subject is not exposed to radioactivity.[121,122] The ability to apply this technique to patients usually not suitable for studies with radionuclides, such as neonates, opens new avenues for investigation. For example, biotin-avidin studies have shown that hematocrit correlates well with blood volume in very-low-birth-weight infants and have provided useful measures of the effect of immediate umbilical cord clamping in preterm neonates.[123,124] However, the technique is not without drawbacks. For example, antibodies against biotinylated red cells, which have transiently appeared in some recipients, could potentially alter results in multiply tested individuals.[125]

Other groups have applied novel experimental techniques for the determination of blood volume and red cell survival. The dilution of fluorescein-labeled hydroxyethyl starch has been used to calculate blood volume accurately.[126] Additionally, the circulating proportion of antigenically distinct allogeneic red cells (usually antigen positive in a background of autologous negative cells) has been successfully tracked by flow cytometry.[127] However, the accuracy of this technique appears to be limited, particularly at very low proportions of the transfused cells.[128] These techniques remain experimental but worthy of further exploration as methods for performing in vivo labeling and kinetic studies without radiation exposure to the subject.

The necessity to perform and accurately interpret cell survival, kinetic, and imaging studies will increase as new cell storage and preservation systems are introduced and new clinical applications for standard and modified blood cells are developed. Close collaboration between specialists in transfusion medicine and other disciplines, especially nuclear medicine, will permit the opportunities in this exciting area to be fully explored.

Chapter 34

Transfusion of the Patient with Congenital Coagulation Defects

Suzanne Shusterman • Catherine S. Manno

INTRODUCTION

Tremendous progress has been made over the past few decades in the diagnosis and management of congenital bleeding disorders. Accurate diagnosis by genetic testing is widely available for most cases of severe hemophilia. Recombinant factor VIII (FVIII) and factor IX (FIX) concentrates have been licensed and are now commonly used in the management of bleeding episodes or, in prophylaxis regimens, for the prevention of bleeding episodes. This chapter reviews the clinical and laboratory features of hemophilia A and B, von Willebrand disease (vWD), and other less common congenital bleeding disorders. Treatment options for bleeding episodes and for prevention of bleeding are presented. Although certain clinical challenges, such as the management of patients with high-titer inhibitors, still exist, the outlook for children born today with hemophilia and other congenital bleeding disorders is brighter than ever before.

HEMOPHILIA A AND HEMOPHILIA B

Hemophilia A and hemophilia B are serious congenital clotting disorders caused by deficiencies in FVIII and FIX, respectively. Both diseases have an X-linked recessive pattern of inheritance. The incidence of hemophilia A (classic hemophilia) is 1 in 5000 male births, and the incidence of hemophilia B (Christmas disease) is approximately 1 in 30,000 to 50,000 male births.[1]

Hemophilia is a clinically heterogeneous disorder with severity and symptoms dependent on an individual's factor activity level. FVIII and FIX activity levels are measured in international units (IU/mL), with 1 IU/mL corresponding to 100% of the factor found in 1 mL of normal plasma. Normal FVIII and FIX activity levels range from 0.5 to 1.5 IU/mL (50% to 150%), with measurements lower than this range defining three levels of clinical severity of hemophilia. Patients with mild hemophilia have factor activity levels of approximately 0.05 to 0.30 IU/mL (5% to 30%) and tend to have bleeding difficulties only after severe trauma or surgical procedures. Moderate hemophilia is defined by factor activity levels between 0.01 and 0.05 IU/mL (1% to 5%) and is characterized by bleeding with moderate trauma and rarely spontaneous bleeding. Persons with factor activity levels of less than 0.01 IU/mL (<1%) are designated as having severe hemophilia and can bleed spontaneously into joints and soft tissues.[1] Affected boys and men tend to have the same factor levels and similar clinical manifestations of disease as other family members.[3]

Although most patients with hemophilia A have a positive family history, 20% to 30% of affected persons have no previous family history of disease.[2] A common presentation in the absence of a positive family history is excessive bleeding after circumcision. Hemophilia should also be suspected in any male patient with a history of spontaneous bleeding into joints or muscles, or excessive bleeding with surgery and trauma. Children may have excessive bruising. The diagnosis of hemophilia is made by direct assay of FVIII or FIX activity in plasma, which can even be performed on umbilical cord blood. The cloning of the genes for FVIII and IX on the X chromosome has made carrier and prenatal diagnosis of hemophilia possible in most families. Nearly half of patients with severe hemophilia A have an inversion in the FVIII gene at intron 22,[4,5] and five percent of patients have an inversion in intron 1.[6] If these mutations are not present, carriers can be identified for both hemophilia A and B by direct sequence analysis or linkage analysis, provided that affected and unaffected family members are available. Direct gene mutation and linkage analysis can also be performed in the prenatal period by chorionic villus sampling at 10 to 12 weeks' gestation or amniocentesis after 15 weeks' gestation.[4] If genetic analysis is not possible, fetal blood sampling, when available, can be used to assay plasma FVIII levels.[7] There is no single dominant mutation responsible for hemophilia B, so direct sequence analysis is often performed to identify carriers or make a prenatal diagnosis. FIX plasma assays are less reliable in making the definitive diagnosis before or at birth because of normally low levels of vitamin K–dependent factors in the prenatal and postnatal periods.[8]

Therapeutic Options for Factor Replacement in Hemophilia

Historical Perspective

Before the availability of specialized products to replace specific clotting factor deficiencies, patients with hemophilia were treated with whole blood or fresh frozen plasma. Many patients died of hemorrhage or were incapacitated with progressive joint disease because transfusions were either unavailable or contained inadequate amounts of factor. In the 1960s, fractionation of large pools of plasma allowed crude separation of FVIII and FIX from other plasma proteins. Cryoprecipitate, that portion of a unit of fresh frozen plasma that precipitates during thawing at 4°C to 6°C, contains FVIII, von Willebrand factor (vWF), FXIII, and fibrinogen and was the first concentrate available for more specific

factor replacement for hemophilia A.[9,10] Prothrombin complex concentrates (PCCs), containing FII, FVII, FIX, and FX, were developed for treatment of hemophilia B in 1967.[11]

In the 1970s, efforts were focused on improving solubility, yield (units of clotting factor recovered from plasma), and purity of clotting factor preparations. Lyophilized specific FVIII and FIX concentrates became commercially available, and their ease of storage and reconstitution made home infusion for early signs of hemorrhage possible, thus markedly improving the quality of life of patients with hemophilia.[2,10,12] These concentrates, however, were prepared from pooled plasma obtained from 2000 to 200,000 mostly paid donors,[9] and by 1980, the transmission of hepatitis from these concentrates was recognized.[2] In 1982, the first case of acquired immunodeficiency syndrome in a patient with hemophilia was reported; by 1988, the prevalence of seropositivity for human immunodeficiency virus (HIV) was 77% in patients with severe hemophilia A and 42% in patients with hemophilia B.[3,13–15] As a result of the tragic transmission of HIV and hepatitis to so many patients with hemophilia, by the mid-1980s, the major goal of factor concentrate development was further improvement of product purity and elimination of viral transmission.[16]

Purification Methods

The purity of factor concentrates is classified according to specific activity, the ratio of clotting protein to nonclotting protein contained in a factor concentrate.[17] Improved separation techniques have resulted in the availability of increasingly pure products. Cryoprecipitate is a low-purity concentrate.[1] The first specific factor concentrates made in the 1970s were intermediate-purity products with specific activity levels between 1 and 10 IU/mg total protein.[10] High-purity concentrates with a specific activity ranging from 50 to 150 IU/mg total protein were later produced using ion exchange, affinity, or gel filtration chromatography to improve removal of contaminating proteins.[16] The use of monoclonal antibodies to FVIII or FIX in combination with immunoaffinity chromatography produces very high-purity products (specific activity from 200 to 2000 IU/mg total protein).[16] In addition to enhancing the separation of clotting from nonclotting proteins, purification processes partially separated the clotting proteins from contaminating transfusion-transmitted viruses.[12,16]

Virus Inactivation Methods

Purification techniques alone are not sufficient to eliminate the risk of viral contamination from plasma-derived factor concentrates. Since the mid-1980s, all concentrates made in the United States have undergone some form of viral inactivation, either physical or chemical.[3] HIV is exquisitely heat labile, and effective eradication can be accomplished with heat or a combination of heat and pressure.[3,18] Hepatitis viruses are more resistant to heat inactivation than HIV, although the degree of eradication improves with increased temperature, moisture, and length of heating.[16] One problem with heat treatment of factor concentrates is a reduction in factor yield. HIV and hepatitis B and C viruses are lipid-coated viruses and are readily inactivated with a combination of solvent and detergent treatments. Plasma-derived FVIII concentrates treated with solvent and detergent were first licensed in 1985, and the combination of the solvent tri-*n*-butyl phosphate and the detergent polysorbate-80 is now widely used.[16] No transmission of lipid-coated viruses has been seen in clinical trials using solvent-detergent treated products,[19] and product yield is high in these preparations.[18] Hepatitis A and parvovirus B19, however, are not lipid-coated; as such, they elude inactivation with solvent-detergent combinations and therefore remain potential contaminants in plasma-derived concentrates.[3,12,20]

Factor VIII Concentrates

Many different specific FVIII concentrates are licensed in the United States (Table 34–1). All products have undergone viral attenuation.[3] Plasma-derived products of high and very high purity (the latter including immunoaffinity purified) and recombinant products (ultra-pure) are available today.[1] Certain plasma-derived FVIII products contain vWF and fibrinogen in addition to FVIII,[3] which allows them to also be used for treatment of vWD. In 1984, two biotechnology companies (Genentech, San Francisco, and Genetics Institute, Boston) cloned and expressed the FVIII gene, which made the production of recombinant FVIII (rFVIII) possible.[21,22] After this, first-generation rFVIII products were developed and licensed by the U.S. Food and Drug Administration (FDA) for use in patients with FVIII deficiency in the United States.[12,23] All first-generation products contained trace amounts of hamster proteins and mouse immunoglobulin G.[12] However, development of antibodies against rodent protein or transmission of animal viruses to recipients of these products has not been reported.[17] Their biochemical profiles are similar to those of plasma-derived FVIII.

After preclinical safety evaluations, clinical studies with rFVIII (Recombinate and Kogenate) were performed in previously untreated patients to assess efficacy, safety, and inhibitor formation.[24,25] Both rFVIII products were found to have clinical efficacy equal to intermediate- or high-purity plasma-derived products and were well tolerated. Both studies in previously untreated patients showed a higher incidence of inhibitor formation than previously described; however, prior estimates were collected retrospectively and included patients with mild hemophilia as well as extensively pretreated patients, all of which likely contributed to previous underestimation of the risk of inhibitor formation.[24,25] In addition, longitudinal follow-up of previously untreated patients in both rFVIII trials demonstrated that the inhibitors were transient in more than 50% of those in whom they developed.[26]

Although first-generation recombinant FVIII products are not derived from human plasma and are ultra-pure, they required the addition of a stabilizer such as human albumin to prevent the highly concentrated clotting proteins from adhering to the surface of the container.[27] These concentrates have specific activity greater than 3000 IU/mg protein before the addition of human albumin.[28] Safety concerns about the addition of albumin have been raised, although none of the first-generation recombinant products have been associated with hepatitis transmission, HIV transmission, or transmission of any other known infectious disease. Recent rFVIII product development has focused on decreasing or eliminating use of human albumin. Second-generation FVIII products use only a small amount of human albumin in the production process and instead include sugar as an alternative stabilizer.[3] These products include Kogenate SF (sucrose formulated) and Helixate FS[29] as well as ReFacto, which is a B-domain-deleted rFVIII product.[30,31] In 2003, Advate was licensed as

a rFVIII with structure homologous to the previous product Recombinate but made without addition of exogenous human or animal proteins. Efficacy and safety have been demonstrated in patients for the treatment of hemophilia A without increased immunogenicity.[32]

Factor IX Concentrates

Three types of factor concentrates are available for treatment of patients with FIX deficiency: PCCs, coagulation FIX concentrates, and recombinant FIX (rFIX) (Table 34–2).

Prothrombin complex concentrates, also known as FIX complex concentrates, contain FIX as well as prothrombin, FVII, and FX, some of which becomes activated during preparation.[17] PCCs are low-purity products with a specific activity less than 50 IU/mg total protein.[1] When PCCs are used at frequent intervals or for prolonged periods, they have been associated with paradoxic thrombotic complications, such as myocardial infarction, venous thromboembolism, and disseminated intravascular coagulation.[16,33] These problems are caused either by the presence of activated factors that serve to trigger coagulation or by accumulation of high levels of the factors.[16] High-purity FIX concentrates, also known as coagulation FIX concentrates, were first licensed in 1992.[16] They are purified by immunoaffinity or gel chromatography, contain only FIX, and have little or no thrombotic potential.[16,17] High-purity concentrates are preferred over PCCs, particularly when frequent replacement is required, such as in surgical patients or in clinical situations associated with an increased risk of thrombosis, as in patients with advanced liver disease.[12] FIX concentrates currently available in the United States include Alphanine SD and Mononine.[16,34,35]

The gene for FIX was cloned in 1982 and was successfully transfected into Chinese hamster ovary cells, a process leading to rFIX production in 1985 by Genetics Institute.[36–39] Initially, rFIX was tested in a canine model and in previously treated patients and was shown to have clinical efficacy comparable to that of plasma-derived products, with a low thrombogenic potential even at high doses.[37,40] Inhibitor formation was also low; only 1 of 44 previously treated patients developed a low-titer inhibitor that was detectable for 11 months.[41]

In October 1995, a trial of rFIX in previously untreated patients was initiated. Although the final results of this trial are not yet published, preliminary reports show good clinical efficacy with no adverse effects, including no viral transmission. The only difference detected between plasma-derived and rFIX in these initial studies was that recovery of rFIX is approximately 20% less than in the plasma-derived products. Poorer than anticipated recovery has been attributed to minor differences in post-translational modifications between rFIX and plasma-derived products.[40] One rFIX concentrate, BeneFix, is currently available in the United States. The specific activity of BeneFix is greater than 200 to 360 IU/mg protein, and the final preparation does not contain human albumin.[28]

Nonconcentrate Therapeutic Options for Hemophilia

Desmopressin

Desmopressin (DDAVP, 1-deamino-8-d-arginine vasopressin) is a synthetic analog of vasopressin that stimulates

endothelial cell release of FVIII, vWF, and plasminogen activator. It is often useful for patients with mild hemophilia, in whom it may provide a therapeutic elevation of factor levels. DDAVP, at a dose of 0.3 μg/kg, is diluted in 10 to 50 mL of saline, and is administered intravenously over 15 to 30 minutes.[42,42] Side effects include facial flushing, mild headaches, nausea, and lightheadedness.[3] DDAVP can rarely cause inappropriate water retention and subsequent hyponatremia that can be avoided with fluid restriction after treatment.[2,3] A concentrated nasal spray (Stimate) is also available that is given at a dose of 300 μg (one spray in each nostril) for patients weighing 50 kg or more and 150 μg (one spray in one nostril) for patients weighing less than 50 kg.[17,42]

Antifibrinolytic Therapy

Antifibrinolytic therapy inhibits clot lysis and stabilizes clot formation by saturating the fibrin-binding sites on plasminogen and preventing its attachment to a developing clot.[44] Antifibrinolytic therapy is particularly helpful in the treatment of oral hemorrhage because saliva contains a high concentration of fibrinolytic proteins, so clot formation is rendered more difficult. Two antifibrinolytic agents—aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron)—are in clinical use. Amicar is recommended at a dose of 100 mg/kg every 6 hours either orally or intravenously and is available both as a syrup and as a tablet.[2] The recommended dose of Cyklokapron is 25 mg/kg orally (as a tablet only) or 10 mg/kg intravenously every 8 hours.[2] These drugs are contraindicated in patients who have received PCCs or activated PCCs within 12 hours because of the possibility for enhanced thrombosis.[3]

Therapeutic Contraindications

Patients with hemophilia and other congenital coagulopathies should avoid the use of drugs that interfere with platelet function. These drugs include, but are not limited to, aspirin and nonsteroidal anti-inflammatory agents.[17]

Clinical Management

General Principles

The goal of hemophilia care is to prevent morbidity caused by both acute blood loss and chronic, repeated bleeding episodes. Treatment or prevention of acute hemorrhage requires intravenous replacement of FVIII or FIX to hemostatic plasma levels. Factor concentrate infusions can be given to induce and to maintain hemostasis at the time of a bleeding episode, an approach known as *on-demand therapy*, or at prescribed intervals to prevent hemorrhage, an approach known as *prophylactic therapy,* the long-term benefits of which have been documented over the past two decades. Once only recommended for patients in northern Europe, prophylaxis regimens are now broadly prescribed in developed nations where factor concentrates are widely available.

Factor Dosing

The dose of concentrate required for factor replacement is calculated on the basis of the volume of distribution, the half-life of the specific concentrate, the patient's type and severity of hemophilia, and the severity of the particular bleeding episode.[2,3] Based on the severity of a specific bleeding episode, the minimum plasma factor level required to sustain hemostasis is determined. Potentially severe bleeding episodes that are life-threatening or limb-threatening require factor replacement to maintain a plasma factor level of 50% to 100% of normal. As discussed later, depending on the specific situation, these levels may need to be maintained for several days. Less severe bleeding episodes require factor replacement to reach a plasma factor level of 30% to 50% of normal. Under these circumstances, usually only a few doses of factor are required to control bleeding.[3]

The dose of concentrate required to reach these plasma factor goals is calculated using the volume of distribution ofthe specific factor concentrate. In general, 1 IU of plasma-derived FVIII concentrate per kilogram raises the plasma factor

level by 1% in children, whereas 1 IU of plasma-derived factor concentrate per kilogram raises the plasma factor level by 2% in adults.[45] Using rFVIII, 1 IU of factor concentrate raises the plasma factor level by 2% in both children and adults.[46] For FIX products, 1 IU of plasma-derived FIX concentrate per kilogram raises the plasma factor level by 1%,[17] and 1 IU of rFIX concentrate per kilogram raises the patient's plasma level by approximately 0.6%.[40] The volume of distribution of rFIX is variable among patients, and therefore a recovery study should be done for each patient to determine the optimal dosing regimen.[2]

Subsequent dosing of factor concentrate is based on the half-life of the specific concentrate. Both factors have an initial short half-life secondary to diffusion that becomes longer with repeat dosing. The initial half-life of FVIII is 6 to 8 hours, and the subsequent half-life is 8 to 12 hours. The initial half-life of FIX is 4 to 6 hours, and the subsequent half-life is 18 to 24 hours.

Treatment of Acute Bleeding Episodes (On-Demand Therapy)

Early treatment of bleeding episodes is essential to limit the amount of blood loss and the subsequent tissue damage caused by chronic blood exposure. Replacement factor recommendations for a specific bleeding episode depend on its location and the potential for complications secondary to blood loss. Laboratory measurements of the partial thromboplastin time (PTT) and FVIII or FIX levels are important guides to successful therapy and should be ordered when managing a serious bleeding episode such as intracranial hemorrhage. Management of common bleeding problems in hemophilia is discussed later, and factor replacement guidelines for specific hemorrhages are listed in Table 34–3.

Intracranial Hemorrhage

Intracranial hemorrhage is a major cause of morbidity and mortality in patients with hemophilia. Patients with severe factor deficiency are at higher risk of central nervous system bleeding than are patients with higher baseline factor levels. Before prophylaxis was widely practiced, about half of all cases of intracranial hemorrhage were not preceded by head trauma. Given the consequence of delayed or absent treatment, all patients with moderate or severe hemophilia with any type of head injury or a significant headache should be treated immediately with a factor replacement of 100%. Patients with a history of significant trauma should then be evaluated with a computed tomography scan. If the scan shows no sign of hemorrhage, the patient should be admitted to an inpatient setting for observation and should receive one to two subsequent 50% corrections to protect against possible delayed or slow bleeding.[42] Patients with mild hemophilia generally need factor replacement only after severe trauma. Management of actual intracranial bleeding requires prolonged maintenance of 100% of normal factor levels and includes the same life support measures and indications for surgery used in children without coagulation disorders.

Joint Bleeding

Hemarthroses are the most common cause of progressive morbidity in hemophilia. Bleeding into a joint space may occur in the absence of known trauma in patients with severe disease. The joints most commonly involved are the knees, elbows, and ankles.[2] To limit long-term joint damage, initial replacement therapy should be instituted as early as possible to raise the plasma factor level to 50% to 70%. For minor or early joint bleeding, an additional factor replacement should be given to maintain a plasma factor level of 30% for approximately 24 hours. For late or significant joint hemorrhage or bleeding in a joint that has been the site of recurrent hemorrhages (target joint), a factor level of 30% should be maintained for 36 to 48 hours. In addition, for all hemarthroses, the joint should be immobilized with a splint for 48 to 72 hours. These recommendations apply to all hemarthroses, regardless of the severity of an individual patient's disease. Children who have had more than one spontaneous hemarthrosis in a single joint are good candidates for future prophylaxis because they are likely to develop progressive joint disease in the affected joint and elsewhere without it.

Muscle Bleeding

Most muscle hemorrhages are superficial and are easily controlled with a single dose of replacement therapy to 30%

Table 34–3 Factor Replacement Guidelines for Common Bleeding Problems in Hemophilia

Type of Bleeding	Target Factor Level (IU/dL)	Duration of Factor Replacement	Comments
Intracranial	0.8–1.0	10–14 days	Secondary prophylaxis to prevent recurrent bleeding
Head trauma, no intracranial hemorrhage	1.0 initially, then 0.5 –1.0 if significant trauma	24–36 hours	Computed tomography scan even if normal exam for significant trauma
Joints	0.5–0.7 initially, then 0.3–0.5	24–48 hours	Immobilize for 48–72 hours
Deep muscle	0.7–1.0 initially, then 0.3–0.5	5–7 days	Hospitalize, bed rest, monitor for blood loss
Superficial muscle	0.3	12–24 hours	Immobilize for 24–48 hours
Oral mucosa	0.3	12–24 hours	Antifibrinolytics or topical therapy may be sufficient
Persistent hematuria	0.3–0.5	Until hematuria clears	Bed rest, adequate hydration, no antifibrinolytics, consider renal ultrasound
Trauma or surgery	1.0 initially, then 0.5–0.7	7–14 days	Shorter duration for minor procedure; recovery study preoperatively

correction, if correction is necessary at all. However, substantial blood loss can occur with internal muscle bleeding into large cavities such as the thigh or the iliopsoas. These hemorrhages should be treated with an initial 70% correction, and plasma factor levels should be maintained at more than 30% for several days while healing occurs. These severe muscle hemorrhages are best treated with hospital admission and bed rest. The patient's hemoglobin level should be checked initially and later, as clinically indicated, because significant blood loss can occur with minimal swelling, particularly with thigh hemorrhages.

Mouth Bleeding

Oral bleeding is particularly common in young children with hemophilia and may occur with primary tooth eruption or in association with loose deciduous teeth. In addition, bleeding can occur after trauma, leading to a laceration of the tongue or frenulum. Antifibrinolytic therapy or local measures such as topical thrombin, pressure, or ice may be sufficient to control bleeding. However, if these measures are not adequate, factor concentrate replacement should be given to obtain a 30% correction. If bleeding persists or recurs, additional replacement doses may be required.

Hematuria

Painless, atraumatic hematuria can occur in patients with severe hemophilia. Bed rest and increased fluid intake is sufficient initial treatment. If symptoms persist for more than 24 hours, bed rest should be continued and the plasma factor level should be corrected to 30% until the bleeding clears. If the patient has a history of trauma, bleeding is persistent, or bleeding occurs in a patient with mild or moderate hemophilia, an ultrasound scan should be performed to look for an intracapsular or intrarenal hemorrhage so that appropriate factor replacement can be given.

Soft Tissue Bleeding

Soft tissue hemorrhages do not require factor replacement unless they lead to compression of critical organs. For example, a soft tissue hemorrhage in the neck could lead to airway compression. In this situation, 100% correction should be given immediately, and appropriate measures should be taken to ensure airway patency.

Prophylactic Therapy

The major long-term morbidity of hemophilia is joint disease caused by repeated exposure of the synovium to blood. Blood acts as an irritant in a joint and leads to synovial membrane proliferation, which, in turn, makes the joint more susceptible to repeated injury and bleeding. Recurrent bleeding then causes chronic synovitis, damage to the underlying cartilage, and finally erosion of the bone.[47] Before the availability of specific factor concentrates, people with severe hemophilia had an average of 30 to 35 joint hemorrhages per year, and 90% developed subsequent degenerative joint disease.[48,49] The introduction of specific factor concentrates, which allowed earlier and more complete treatment of hemarthrosis, markedly decreased the incidence of hemophilic arthropathy, but it did not eliminate it entirely, thus necessitating an alternative treatment strategy.

Dr. Nilsson and colleagues in Malmo, Sweden, first developed the concept of prophylaxis in 1958.[47] Based on the observation that people with moderate and mild hemophilia rarely developed joint disease, these investigators hypothesized that by giving regular factor infusions with the goal of maintaining a factor level of at least 1% in patients with severe hemophilia, they could in a sense convert severe disease to mild or moderate disease and could prevent frequent hemorrhage and subsequent arthropathy.[50,51] These investigators published several case series demonstrating the benefits of their theory, and their data have been confirmed by others around the world.[47,52,53] A longitudinal, uncontrolled outcome study from 21 centers in the United States, Europe, and Japan published in 1994 reported that patients with severe hemophilia who were treated with adequate prophylaxis experienced a reduced number of hemorrhages and a reduced rate of joint degeneration, whereas patients receiving on-demand treatment had signs of progressive joint deterioration.[54]

Two prophylactic treatment strategies have been developed that vary according to the timing of initiation of regular infusions relative to joint status. *Primary prophylaxis* is defined as the initiation of regular factor concentrate infusions before the development of recurrent joint bleeding and clinical or radiologic abnormalities.[55] *Secondary prophylaxis* indicates the initiation of regular factor concentrate infusions after the development of chronic clinical or radiologic abnormalities in a particular joint, considered a "target" joint.[56] Until recently, secondary prophylaxis was the treatment strategy most commonly used in the United States. It has been shown to be beneficial in preventing frequent rebleeding in a target joint and to improve results on orthopedic examination and quality of life.[52,57,58] However, eventual joint deterioration, as evidenced by radiologic evaluation, is not stopped in most cases by secondary prophylaxis.[54] In contrast, primary prophylaxis has been shown to prevent permanent, chronic joint damage. An update of the Swedish prophylaxis experience demonstrates that boys who began primary prophylaxis at a mean age of 1.2 years had no clinical or radiologic evidence of joint damage when they were evaluated 3 to 12 years after the initiation of therapy.[51,53]

In 1994, the National Hemophilia Foundation's Medical and Scientific Advisory Counsel recommended that primary prophylaxis be the treatment of choice for severe hemophilia.[2] However, this recommendation has met several obstacles. Smith and colleagues[59] compared 27 boys receiving prophylactic factor concentrate infusions with 70 boys receiving episodic infusions over a 2-year interval and showed that the median cost of prophylaxis is at least three times the cost of on-demand therapy. One way to decrease the cost of prophylaxis, as suggested by Carlsson and colleagues,[60] is to give prophylactic factor infusions more frequently; therefore, smaller doses are required to maintain a factor trough level higher than the baseline value. The cost of recombinant factor concentrate for prophylaxis on a three times weekly schedule for a 70-kg man is approximately $100,000 a year.

Another major obstacle to prophylaxis is venous access. Placement of central venous access devices is often necessary to provide consistent venous access in young children receiving prophylaxis; this is associated with an increased risk of infection compared with intermittent intravenous access.[61,62] The incidence of central line infections in a survey of 81 hemophilia treatment centers from 33 states was 28% in patients receiving prophylaxis.[63] A third concern preventing the widespread adoption of prophylaxis is that frequent early exposure to large quantities of factor may stimulate inhibitor formation. Conversely, early regular factor infusion may prevent inhibitor formation because it may mimic immune tolerance.[28,51]

When prophylaxis is implemented, factor should be administered at a dose to maintain a trough factor activity of more than 1%, and recombinant factor should be given to minimize the risk of infection.[47,60] In general, this requires doses of rFVIII every other day or three times a week and twice-weekly dosing of rFIX.

Surgical Procedures

The goal of hemophilia care for elective surgery is to maintain factor levels of 50% to 70% throughout the surgical procedure and the postoperative period.[42] A factor recovery study should be done preoperatively to ensure that the patient has the expected response to therapy and to predict the half-life of the concentrate accurately. Regular factor infusion should continue 2 to 7 days postoperatively and then can be tapered.[42]

Treatment of Newborns

The newborn with unsuspected hemophilia born to a woman with no family history may pass through the newborn period with no clinical evidence of disease.[64] The likelihood of excess bleeding at circumcision is 50%[65]; bleeding from circumcision often prompts a diagnostic workup and definitive diagnosis. Male children born to obligate carrier mothers or those infants diagnosed prenatally with hemophilia present a perplexing question of management. Some practitioners recommend prophylactic infusion of factor concentrate in either case, to prevent neonatal intracranial hemorrhage that could result from a vaginal delivery. Others recommend immediate measurement of neonatal factor levels and concomitant head ultrasounds to rule out intracranial hemorrhage.[66,67]

Treatment for Patients with Inhibitors

One of the greatest challenges in the management of hemophilia is the development of inhibitors, high-affinity neutralizing immunoglobulin G antibodies directed against FVIII or FIX.[2] Based on both prospective and retrospective studies, inhibitor development occurs in 21% to 33% of patients with severe hemophilia A[28] and in 1% to 4% of patients with hemophilia B.[26] Most inhibitors form in young children who have had less than 20 treatment days and occur more often in black patients than in white patients.[26] There is also an increased incidence of inhibitors in brothers of boys who have already developed an inhibitor, a finding suggesting a genetic predisposition.[68] Patients with severe hemophilia are more likely to develop inhibitors than those with milder forms of disease. This may be because the low levels of factor produced in patients with mild and moderate hemophilia induce immune tolerance, whereas in severely affected patients, the endogenous factor level is so low that infused factor is regarded as a foreign protein and more easily provokes an immune response.[69] Among patients with severe hemophilia, there is a higher rate of inhibitor development among persons with large gene mutations that lead to undetectable factor levels. The rate of inhibitor development is lower in patients with severe hemophilia with missense mutations and small deletions in whom circulating, but abnormal, factor is present.[70,71]

The development of an inhibitor should be suspected when the patient has decreased clinical response to factor replacement; it can also be found in an asymptomatic person during routine laboratory screening.[69] The presence of an inhibitor is confirmed using the Bethesda assay, which measures the titer of neutralizing antibody and is reported in Bethesda Units (BU). One BU is defined as the amount of inhibitor needed to inactivate 50% of the FVIII or FIX in a mixture of inhibitor-containing plasma and normal plasma.[72] Inhibitor patients are classified as high responders or low responders, depending on the extent of amnestic response on repeat exposure to the factor against which the inhibitor has formed.[28] Patients with high-responder inhibitors develop an increased antibody level within a few days of repeat exposure to FVIII or FIX, whereas low-responder inhibitors only minimally increase after repeat exposure to factor. High-responder inhibitors have antibody titers greater than 10 BU and are also called *high-titer inhibitors*, whereas low responders have titers lower than 10 BU and are referred to as *low-titer inhibitors*.[26] The inhibitor titer level is a useful guide for determining the optimal replacement therapy. Specific treatment recommendations for patients with hemophilia A with inhibitors are outlined in Table 34–4.

Patients with low-titer inhibitors can be treated for acute hemorrhage with higher doses of their specific replacement therapy.[2] Patients often require doses two to three times higher than the normal replacement dose to effect hemostasis. FVIII or FIX levels should be monitored before and after treatment, along with the aPPT and clinical measurements, to help assess the treatment's usefulness. Adjuvant measures, including restriction of limb motion and bed rest, should also be used to preserve fragile clots.

First-line treatment of hemorrhage in patients with high-titer inhibitors is aimed at bypassing the factor against which the inhibitor is directed, using either activated PCCs (aPCCs), which contain FII, FVII, FIX, and FX, or rFVIIa. aPPCs are effective in stopping bleeding in approximately half of the inhibitor patients treated.[73] PCCs and aPCCs should be infused at doses of 50 to 100 IU/kg every 12 to 24 hours, with the maximum dose not to exceed 200 IU/kg in 24 hours.[26] As described previously, aPPCs can be associated with thrombotic complications with repeat dosing. In addition, patients with hemophilia B occasionally develop an increased inhibitor titer or a severe allergic response when they are treated with these products containing FIX and therefore must be monitored closely.[74] Recombinant activated FVIIa (rFVIIa; (NovoSeven) also bypasses FVIII and FIX by activating the extrinsic pathway of the clotting cascade. rFVIIa is thought to initiate hemostasis only at the site of tissue injury and therefore should not be thrombogenic.[75] In addition, rFVIIa is not plasma derived and is not associated with an anamnestic response. A drawback to using rFVIIa is its short half-life, which requires dosing every 2 to 3 hours, a feature that makes treatment cumbersome and costly.[76] Laboratory coagulation parameters have not been shown to correlate directly with the establishment of hemostasis when one uses bypassing agents. Dosing is therefore empiric, based largely on clinical response.

None of the transfusion options for patients with high-titer inhibitors are as reliable as specific factor replacement, and therefore elimination of inhibitors with immune tolerance therapy is a major emphasis of management. Immune tolerance therapy involves regular exposure to high doses of FVIII or FIX for weeks to years with or without concurrent immunosuppressive therapy. Several available immune tolerance therapy regimens are available, with an overall success rate of 60% to 80%, but these regimens often require central venous access and can be time intensive and costly.[2] Data from the North American immune tolerance therapy registry shows a higher efficacy and shorter interval to inhibitor elimination

Table 34–4 **Treatment of Hemorrhage in Patients with Hemophilia with Inhibitors**

		Minor Hemorrhage		Major Hemorrhage	
Type of Patient	**Titer at Time of Hemorrhage**	**Agent**	**Dosage**	**Agent/Method**	**Dosage**
High responder	<10BU	PCC	75 IU/kg q12h	Human FVIII	100–200 IU/kg, q12h*

From Manno CS: Treatment options for bleeding episodes in patients undergoing immune tolerance therapy. Haemophilia 1999;5:33–41.

when immune tolerance therapy is initiated when the inhibitor titer is low.[77] Other data show improved outcomes when the interval between inhibitor detection and starting immune tolerance therapy is short.[77] It is therefore important to start immune tolerance therapy as soon as a patient's high-titer, high-response status is confirmed. Once immune tolerance has been achieved, management of bleeding episodes can be the same as before inhibitor development. An international immune tolerance study is currently assessing optimal dose and interval for patients with high-titer inhibitors.[78]

Comprehensive Hemophilia Care

Patients with hemophilia have lifelong disease punctuated by hospitalization and the need for expensive intravenous medication. The management of such complicated patients is best supervised by a multidisciplinary expert team that includes a hematologist, a hemophilia nurse specialist, a physical therapist, a social worker, an orthopedist, and a dentist. Regular clinic visits for evaluation by these health care providers give the patient with hemophilia a solid foundation for managing the long-term medical and psychosocial issues associated with chronic disease.

Gene Therapy

Hemophilia is an attractive disease for a gene therapy approach for several reasons.[79] First, small increases in circulating levels of FVIII or FIX through expression of a successfully transferred gene would likely result in significant reduction of bleeding episodes. Second, tight regulation of transgene expression is not necessary because normal levels of FVIII and FIX extend to 150%. Gene therapy trials using numerous different viral and nonviral approaches to transfer the recombinant gene to human cells, including liver and muscle cells, have been completed, demonstrating no major safety problems but no long-term efficacy either.[79,80] Whether a gene therapy approach will be safe or effective has yet to be determined.[81]

VON WILLEBRAND DISEASE

Von Willebrand disease is the most common congenital coagulation disorder, occurring in approximately 1% to 2% of the population.[82,83] It is actually a collection of disorders caused by either quantitative or qualitative abnormalities of vWF, a glycoprotein that is important in both primary and secondary hemostasis.[84] In contrast to hemophilia, mucosal bleeding, especially epistaxis and menorrhagia, and easy bruising are the most frequent clinical signs, although more significant bleeding can occur with trauma or surgery. Bleeding symptoms are often most severe in children and adolescents.[85] vWD occurs at the same rate in male and female patients and is generally inherited as an autosomal trait with variable penetrance.[86] In contrast to hemophilia, bleeding symptoms may vary among members of affected families.[85]

Structure and Function of von Willebrand Factor

The gene for vWF is located on chromosome 12 and is 178 kb in length with 52 exons.[87] There is also a pseudogene on chromosome 22 with 97% homology.[88] vWF is initially transcribed as a large, single-chain protein with 2813 amino acids (prepro VFW) that undergoes a series of modifications to become the mature multimeric vWF.[85] First, a small signal peptide is removed to form pro-vWF. Next, the remaining peptide undergoes glycosylation, sulfation, and dimer formation, leading to the formation of vWF multimers of various sizes ranging in molecular weight from 500 to 20,000 kD.[89] vWF is the largest soluble protein in humans. Its plasma concentration and functional activity are generally expressed either as a percentage of normal or as units per milliliter related to a normal plasma pool calibrated against an international plasma standard for vWF.[89]

Von Willebrand factor is synthesized in endothelial cells and megakaryocytes. In endothelial cells, vWF is stored in

Weibel-Palade bodies and is secreted into the plasma or subendothelial matrix, predominantly as high-molecular-weight multimers.[90] Platelet vWF, consisting of mostly low-molecular-weight multimers, is synthesized in the megakaryocyte and is stored in platelet α granules.[89] vWF multimers with the highest molecular weight are most effective in hemostasis because they have a large surface area with a high concentration of binding sites for various ligands and receptors.[89]

Von Willebrand factor is important in both primary and secondary hemostasis. It is a cofactor in platelet adhesion and a participant in platelet aggregation. In response to vascular injury, a conformational change occurs in plasma vWF that allows it to bind to platelet glycoprotein Ib.[85,90] Platelets then adhere to the site of endothelial damage and become activated after interactions with subendothelial components such as collagen. Platelet activation causes release of stored platelet components, including vWF from α granules, and expression of activated glycoprotein IIb/IIIa, the receptor that is involved in platelet aggregation.[90] Platelet vWF can bind to glycoprotein IIb/IIIa to facilitate aggregation, although fibrinogen is the main cofactor in this reaction.[85] vWF also plays an important role in the coagulation cascade, by acting as a carrier protein for FVIII so that it is protected from proteolytic cleavage in the plasma.[90] Deficiency of vWF causes FVIII to have a reduced half-life and leads to a deficiency in plasma FVIII. In addition, vWF plays a role in stimulating FVIII release into plasma. This is shown in vitro, where cells transfected with the FVIII gene express rFVIII more efficiently when vWF is present in the media or is cotransfected along with FVIII. In addition, in vivo, when plasma from FVIII-deficient patients is infused into patients with vWD, an increase in FVIII in the patients with vWD is seen.[85]

Classification

As is evident from the previous discussion, vWF plays several critical roles in platelet function and thrombus formation. For vWF to function normally, several requirements must be met, including the presence of high-molecular-weight multimer forms, the appropriate release of activated vWF, and the presence of binding sites for platelet glycoproteins, FVIII, and constituents of the subendothelial cell matrix. Abnormalities of any of these components can lead to vWD, with particular deficiencies leading to different clinical phenotypes. In addition, because the vWF locus is autosomal and the protein is polymeric, the phenotype of a particular patient with vWD is the result of interactions between two different alleles and protein products that lead to the further clinical heterogeneity of this disorder.[91] More than 20 subtypes of vWD have been identified so far.[92] The current classification system for vWD, approved by the Subcommittee on vWF at the 39th Annual Meeting of the Scientific and Standardization Committee of the International Society of Thrombosis and Haemostasis in 1993, attempts to simplify this clinical heterogeneity by classifying patients based on pathophysiology, clinical behavior, and genetic abnormalities.[91] This classification scheme is based on the principle that all vWD is the result of mutations of the vWF locus. In the scheme are three major categories of vWD: type 1 disease, a partial quantitative deficiency of vWF; type 2 disease, a qualitative deficiency of vWF; and type 3 disease, a complete quantitative deficiency of vWF. The clinical course and genetic implications can be predicted by type. Mixed phenotypes can exist, resulting from compound heterozygosity.[91]

Type 1

Type 1 disease is most common and accounts for 70% to 80% of patients diagnosed with vWD.[89,93] Patients with type 1 disease have a mild to moderate decrease in plasma levels of vWF with a normal vWF multimer pattern. Type 1 disease is usually inherited in an autosomal dominant pattern. Clinically, patients with type 1 disease usually have only mild symptoms and are often only identified during routine preoperative screening tests.[85,89]

Type 2 (2A, 2B, 2M, and 2N)

Type 2 vWD disease is diagnosed in 15% to 20% of affected patients and is characterized by a qualitative defect in vWF caused by missense mutations and small inframe deletions or insertions.[84,89] Typically, patients have more significant bleeding symptoms than are seen in type 1 disease. Family history is often positive with this diagnosis, with both autosomal dominant and recessive patterns of inheritance seen.[89] Type 2 disease can be further classified into four variants according to the particular vWF abnormality.

Type 2A vWD is the most frequent subtype and is characterized by decreased vWF platelet-dependent function and an absence of high- and intermediate-molecular-weight vWF multimers as demonstrated on agarose gel electrophoresis.[84,91] This multimer abnormality can result from either abnormal synthesis of vWF or increased breakdown of circulating vWF. Type 2A vWD is usually inherited as a dominant trait.[90,91]

Type 2B is a rarer form of vWD in which an abnormal vWF has excessive affinity for platelet glycoprotein Ib. This causes excessive platelet activation and removal from the circulation and leads to variable thrombocytopenia as well as decreased plasma concentrations of vWF.[84,86] Thrombocytopenia may be intermittent and is often exacerbated by stress such as infection.[86] Type 2B is inherited as a dominant trait and is associated with absence of high-molecular-weight multimers.[84,93]

Type 2M disease describes patients with decreased platelet-dependent function that is similar to type 2A disease, except high-molecular-weight multimers are not absent. Decreased platelet function is instead caused by structural or functional defects in binding regions of the vWF protein. Like type 2A and 2B disease, this type is usually inherited as a dominant trait.[84,93]

Type 2N disease (also known as vWD Normandy) refers to patients with vWF variants with decreased binding affinity for FVIII. This leads to decreased survival of FVIII in the circulation and a moderate to severe reduction of FVIII plasma levels with normal vWF levels. Affected persons therefore have a mild hemophilia phenotype. This type usually has an autosomal recessive inheritance.[84–86]

Type 3

Type 3 vWD is characterized by near-complete deficiency of vWF (less than 10%) as well as a secondary deficiency of FVIII, resulting in a severe bleeding disorder with abnormalities in both primary and secondary hemostasis.[93] This type of vWD is very rare, with a prevalence of 1 to 3 cases per 1 million, and is inherited as an autosomal recessive disorder.[94]

Diagnosis

Von Willebrand disease should be suspected in patients with a history of increased bruising, prolonged bleeding after minor trauma, or mucosal bleeding, particularly epistaxis and menorrhagia, and is supported by a family history of abnormal bleeding. Initial screening tests include prothrombin time (PT), PTT, platelet count, and bleeding time. The PT is usually normal, whereas the PTT may be prolonged by a decrease in FVIII.[93] The platelet count is also usually normal, although, as described earlier, thrombocytopenia can be present in patients with type 2B disease.[86] The bleeding time, which is usually prolonged secondary to abnormal platelet function, may be normal in patients with type 1 disease with normal platelet vWF content, but it is rarely used today in the diagnostic workup.[93] All these screening tests may be normal in persons with vWD, so further testing may be needed when suspicion of disease is significant.[95]

Specific tests used to evaluate patients for vWD include vWF antigen, FVIII assay, vWF activity (also known as *ristocetin cofactor activity*), and vWF multimer analysis. Because normal physiologic variation can occur in plasma levels of vWF, FVIII, and vWF activity, repeated plasma measurements over time may be necessary to establish a diagnosis of disease.[86,95] Results of these tests vary according to type of vWD.

Von Willebrand factor antigen is decreased in type 1 disease, decreased or normal in type 2 disease, and undetectable in type 3 disease.[93] vWF is an acute phase reactant, and factors such as pregnancy, exercise, infection, and cigarette smoking, as well as medications, including corticosteroids, birth control pills, and DDAVP, can increase plasma concentrations of vWF and need to be taken into consideration when one evaluates test results.[86] In addition, vWF antigen varies with ABO blood types and therefore should be interpreted in reference to values specific for the patient's blood type; persons with blood group O have the lowest mean vWF antigen level.[96] FVIII levels are normal or mildly decreased in patients with types 1 and 2 vWD.[93] In contrast, patients with type 2N and type 3 vWD can have an extremely low FVIII level.[86] The ristocetin cofactor activity assay measures the vWF function, specifically the interaction of vWF with platelet glycoprotein Ib. Patients with type 1 and type 3 vWD tend to have a decrease in vWF activity that is proportional to their decrease in vWF antigen, whereas those with type 2 disease have a more substantial decrease in vWF activity than vWF antigen.[86,93] Studies have shown that measurement of vWF activity is the most sensitive test for diagnosing type 1 vWD.[82,95] Finally, the vWF can be separated by agarose gel electrophoresis into high-, intermediate-, and low-molecular-weight multimers. All the multimers are present in type 1 disease and are absent in type 3 disease. In type 2 vWD, gel electrophoresis can vary with disease type, but generally shows a reduction in high- and intermediate-weight multimer.[86] Table 34–5 summarizes the laboratory findings according to vWD type.

Therapeutic Products

Superficial bleeding, particularly in type 1 vWD, can usually be managed by applying local pressure, ice, or a local topical hemostatic agent. Systemic therapy is generally reserved for bleeding at sites not controllable by local measures or as prophylaxis before and after surgical treatment. The two main approaches to systemic therapy of vWD are increasing the release of endogenous vWF and exogenous replacement of vWF. Selecting the appropriate therapy for an individual patient depends on the specific type of vWD and clinical treatment goal.[44]

Desmopressin

As previously discussed, DDAVP, a synthetic analog of vasopressin, causes immediate endothelial cell release of vWF, FVIII, and plasminogen activator.[43] It is effective in patients with vWD who have adequate stores of functional vWF. Therefore, it is useful in type 1 disease but ineffective in type 3 disease. DDAVP can be used in some patients with type 2A vWD, but it is not recommended in patients with type 2B disease because it can exacerbate thrombocytopenia.[90,97] Patients with type 2N disease generally have high FVIII levels in response to DDAVP, but the released FVIII has a shorter than normal half-life that limits its therapeutic utility in major bleeding episodes.[97] DDAVP is given at the same dose used in mild FVIII deficiency, either intravenously or as a concentrated nasal spray (Stimate). Infusion of 0.3 µg/kg body weight results in an average three- to fivefold increase in vWF and FVIII; nasal dosing is slightly less effective.[43,90] Before therapeutic use, patients should have a trial to measure individual response to DDAVP.[98] Response to DDAVP is generally consistent over time, and family members usually have similar responses.[99] DDAVP is used preferentially over plasma-derived products in patients who have an adequate response, because it does not carry risks of viral transmission. In addition, DDAVP is substantially less expensive than exogenous vWF replacement.[43]

Table 34–5 **Laboratory Findings in von Willebrand Disease According to Subtype**

Study	Type 1	Type 2A	Type 2B	Type 2M	Type 2N	Type 3
von Willebrand factor antigen	↓	↓	+/– ↓	↓	↓	Absent

Adapted from Montgomery RR, Gill JC, Scott JP. Hemophilia and von Willebrand disease. In Nathan DH, Orkin SH (eds). Naton and OSKI's Hematology of Infancy and Childhood, vol 2, 5th ed. Philadelphia, WB Saunders, 1998, p 1646.

Desmopressin may not be useful when prolonged hemostasis is required. When it is administered more often than once every 24 to 48 hours, decreased effectiveness may be observed because of depletion of storage pools (tachyphylaxis).[99] Therefore, when DDAVP is used for several days, coagulation parameters should be followed closely (vWF, FVIII, and ristocetin cofactor) to monitor the need for alternative replacement therapy.

Exogenous von Willebrand Factor Replacement

Exogenous replacement of vWF is used in patients in whom DDAVP is not effective, including most patients with type 2B, type 2M, and type 3 vWD, as well as those with type 1 and 2A disease who do not show adequate response in a DDAVP trial. Fresh frozen plasma contains both FVIII and vWF; however, the large volumes required to achieve hemostasis limit its clinical use.[98] Cryoprecipitate, containing vWF, FVIII, and fibrinogen, was the treatment of choice for patients with vWD from the early 1960s until the early 1980s.[44,100] The development of products with higher purity that are more convenient to store, have decreased volumes of infusion, and have undergone viral inactivation subsumed the need for cryoprecipitate. However, if other alternatives are not available, transfusion of cryoprecipitate will produce hemostasis.[90] Each bag of cryoprecipitate contains 80 to 100 IU of vWF, and the usual starting dose is 1 bag/10 kg body weight every 12 to 24 hours.[90,98] Cryoprecipitate from a single donor who has been pretreated with DDAVP contains supraphysiologic amounts of vWF and is another treatment option.[85]

The early plasma-derived FVIII concentrates were not effective in treating vWD because the vWF multimers were partially proteolyzed; this resulted in a loss of functional high-molecular-weight multimers.[44] In addition, high-purity plasma-derived (monoclonal antibody-derived) FVIII as well as rFVIII cannot be used to treat vWD because they do not contain appreciable amounts of vWF.[90] Two plasma-derived, virus-inactivated FVIII concentrates available in the United States contain sufficient amounts of functional vWF: Humate-P and Alphanate.[90,100,101] The latter product is not yet licensed by the FDA for use in vWD. In general, dosing for vWD is in units of ristocetin cofactor. In addition, a recombinant vWF concentrate is currently under development.[94]

Adjunctive Treatment

As previously described for hemophilia treatment, antifibrinolytic therapy, which inhibits lysis of newly formed clots, is also useful in the treatment of vWD. Aminocaproic acid and tranexamic acid, the agents most commonly used, are given at the same doses used in hemophilia. Both agents may be useful alone in mild type 1 disease or as adjuncts in the treatment of oral hemorrhage, epistaxis, gastrointestinal bleeding, and menorrhagia. These agents may increase the risk of thrombosis and are contraindicated in patients with a known pre-existing prothrombotic state and in the treatment of genitourinary bleeding.[90,98]

Estrogen causes an increase in plasma vWF. This effect is variable and is not dose related; therefore, it is not widely clinically applicable. However, estrogen therapy, particularly in the form of oral contraceptives, is useful in reducing the severity of menorrhagia, a common problem in women with vWD.[98] As previously discussed, patients with vWD should avoid drugs that interfere with platelet function.

RARE INHERITED CONGENITAL CLOTTING DISORDERS REQUIRING TRANSFUSION THERAPY

Fibrinogen Deficiencies

Congenital afibrinogenemia is a rare disorder, with an estimated incidence of 1 to 2 per 1 million that is inherited as an autosomal recessive trait with the gene located on chromosome 4.[102,103] It is characterized by virtual absence of fibrinogen secondary to deficient liver cell synthesis. Symptoms range from minimal bleeding to life-threatening hemorrhage, and are commonly seen in the newborn period and include hematomas or intracranial hemorrhage from birth trauma, bleeding from the umbilicus, and excessive bleeding after circumcision. Similar to hemophilia, spontaneous hemorrhage and excessive post-traumatic and postsurgical bleeding are seen and can result in excessive ecchymoses, hemarthroses, gastrointestinal bleeding, and intracranial hemorrhage.[102,104] In addition, menstrual bleeding can be severe, and first-trimester spontaneous abortion is common.[102,105] Laboratory screening tests that use clot formation as an endpoint, including thrombin time, PT, and PTT, are markedly prolonged. Definitive diagnosis is made by measurement of plasma fibrinogen, which is undetectable by both functional and immunologic assays.

Dysfibrinogenemia is characterized by structural fibrinogen defects causing alterations in the conversion of fibrinogen to fibrin. Approximately 250 cases have been reported, and the disorder is inherited as an autosomal dominant trait.[106] Dysfibrinogenemias can be associated with either hemorrhage or thromboses, or they can be asymptomatic.[103,106] The bleeding symptoms most commonly seen are ecchymoses, epistaxis, menorrhagia, and mild to moderate postoperative or post-traumatic bleeding. Symptoms are generally mild, although they can be more severe in patients with homozygous gene mutations. Results of screening tests are variable; the PT and PTT can be normal or prolonged. The thrombin time is prolonged in dysfibrinogenemias associated with hemorrhage, whereas it can be shortened or prolonged in those conditions associated with thromboses. More definitive diagnosis is made by measurement of fibrinogen; levels are normal or increased by immunologic assay, but they are reduced by functional assays.[104,106,107]

For both quantitative and qualitative fibrinogen deficiencies, cryoprecipitate can be used as replacement therapy for significant episodic bleeding. Cryoprecipitate should be administered at a dose to raise the fibrinogen level to between 50 and 100 mg/dL.[102] A typical bag of cryoprecipitate contains 200 to 300 mg of fibrinogen in a volume of 10 to 20 mL.[3] Because the half-life of fibrinogen is 80 hours, dosing is required only every other day.[104] Prophylactic replacement of fibrinogen, practical because of the long half-life of fibrinogen, should be considered for patients with severe symptoms.[108]

Prothrombin Deficiency

Prothrombin deficiency is a very rare autosomal recessive disorder that results from either an absolute protein deficiency or production of an abnormal protein.[109] It is characterized by mild symptoms, including mucocutaneous bleeding and hemorrhage after surgery or trauma. The PT is moderately prolonged, the PTT is normal or mildly prolonged, and the

thrombin time is normal. Definitive diagnosis is made by immunologic and functional prothrombin assays.[104,109]

Therapy is usually not required. Fresh frozen plasma or PCCs can be used to treat clinically significant bleeding. The half-life of prothrombin is 48 to 120 hours.[103] Plasma prothrombin levels greater than 20 to 30 U/dL are generally sufficient to stop bleeding.[109]

Factor V Deficiency

Factor V deficiency occurs in less than 1 per 1 million persons and is associated with a mild to moderate bleeding tendency.[104] It is inherited as an autosomal recessive disease. Symptoms, generally only seen in homozygotes, consist mainly of mucocutaneous bleeding, including menorrhagia, and ecchymoses. Both the prothrombin and PTT are prolonged, with a normal thrombin time. Definitive diagnosis is made by a specific FV assay, with deficiency defined as FV levels lower than 20 U/dL.[110]

Fresh frozen plasma should be used to treat severe bleeding episodes and trauma and as prophylaxis for major surgery. For treatment, the FV level should be initially raised to 25% to 30% of normal using a 20 mL/kg dose of plasma followed by infusions of 6 mL/kg every 12 hours.[109] FV is more labile in frozen plasma than other hemostatic factors, and therefore fresh frozen plasma that is less than 1 to 2 months old should be used.[109]

Several families with combined deficiency of FV and FVIII have been reported.[111] Symptoms are usually milder than in hemophilia A because of higher baseline levels of FVIII. Treatment should include fresh frozen plasma in addition to FVIII concentrates.

Factor VII Deficiency

Factor VII deficiency, resulting from either a protein deficiency or production of a nonfunctional protein, occurs in 1 in 1 million persons and is inherited in an autosomal recessive pattern with high penetrance and variable expressivity.[112] Laboratory evaluation of patients with FVII deficiency reveals a prolonged PT with a normal PTT and thrombin time, a pattern that distinguishes FVII deficiency from other inherited clotting disorders. The diagnosis is confirmed by measuring FVII activity using a tissue factor-dependent one-stage technique. The clinical expression of the disease is generally correlated with the degree of factor deficiency, although reports exist of patients with extremely low FVII levels who present without a history of bleeding.[113] Patients with FVII levels greater than 10% to 15% rarely have significant bleeding problems, whereas patients with levels lower than 1% can have severe bleeding symptoms.[112] The most serious complication of FVII deficiency is intracranial hemorrhage, which occurs most frequently during the first year of life, particularly in the first postnatal week.[114] Mucous membrane bleeding, including excessive bruising, epistaxis, gastrointestinal bleeding, and menorrhagia, is the most common manifestation of FVII deficiency. Hemarthroses, in a pattern similar to what is seen in hemophilia, also occur occasionally.[114]

Treatment is required for severe bleeding episodes and before surgical procedures. PCCs have previously been the mainstays of therapy for FVII deficiency. Replacement doses are calculated to raise the FVII level to more than 15%. FVII concentrations vary among commercially available PCCs and among different lots produced by a single manufacturer, so it is important to monitor the patient's PT and FVII level carefully.[112] As discussed previously, patients receiving PCCs need to be monitored for an increased risk of developing thromboses. Recombinant FVIIa has more recently been shown to be effective as a more specific treatment without an accompanying risk of thrombosis.[115] Studies have shown efficacy of rFVIIa as treatment for intracranial hemorrhage and as prophylaxis for surgical procedures, and these features make rFVIIa the likely treatment of choice for FVII deficiency in the future.[116,117]

Factor X Deficiency

Factor X deficiency results from either a protein deficiency or production of a functionally abnormal protein.[109] It is inherited as an autosomal recessive trait, although some heterozygotes can have bleeding with severe trauma or major surgery. Symptoms generally correlate with the severity of the deficiency and consist mainly of mucocutaneous and post-traumatic bleeding. Hemarthrosis and intracranial hemorrhage have been reported in severely affected patients. Laboratory evaluation reveals prolonged PT and PTT. Diagnosis is confirmed with FX immunologic and functional assays.

Factor X replacement should be given as needed for severe bleeding and trauma as well as before major surgical procedures. The half-life of transfused FX is between 24 and 48 hours. FX is found in both fresh frozen plasma and PCCs.[104] Fresh frozen plasma is given at an initial dose of 10 to 20 mL/kg, followed every 12 hours by a dose of 3 to 6 mL/kg to reach a target plasma FX level of 20 to 30 IU/dL.[109] PCCs contain a variable concentration of FX that can be measured in a specific preparation before elective use.[109] PCCs are more practical to use in situations such as major surgery, when sustained hemostasis is necessary and would require large volumes of plasma infusions. As previously mentioned, when using PCCs, the risk of thrombosis should be considered and monitored.

Factor XI Deficiency

Factor XI deficiency, sometimes called hemophilia C, is a relatively rare disorder distinguished by a variable bleeding tendency in affected individuals. It is inherited as an autosomal trait and is seen most commonly among persons of Ashkenazi Jewish descent, with an 8% frequency of heterozygosity.[118] Three different point mutations in the FXI gene account for nearly all cases of FXI deficiency among Ashkenazi Jews.[119] FXI deficiency is most often detected in association with a positive family history or secondary to a prolonged PTT found during a routine presurgical evaluation. The diagnosis is confirmed with a plasma FXI assay.

Factor XI levels correlate with the genotype. Severe deficiency (FXI levels lower than 15 to 20 IU/dL) is seen in homozygotes or compound heterozygotes, and partial deficiency (FXI levels from 20 to 60 IU/dL) is seen in heterozygotes. Bleeding tendency, however, does not correlate with genotype.[120] Excessive bleeding is most commonly seen in association with severe deficiency, but it can also be seen in patients with partial deficiency. A compilation of studies shows abnormal bleeding in 30% to 50% of patients with partial deficiency.[121] In general, bleeding symptoms are mild or absent, only occurring in association with trauma

or surgery, particularly tonsillectomy. Epistaxis, soft tissue hemorrhage, bleeding after dental extractions, and menorrhagia can also be seen in affected persons.

Fresh frozen plasma is most commonly given as treatment for severe bleeding episodes or as prophylaxis for major surgery. The half-life of FXI in plasma is approximately 45 hours. As an alternative treatment, two specific FXI concentrates are available in Europe.[118] Both have been shown to be hemostatically effective and virally safe, but they have been associated with an increased occurrence of thrombotic events, particularly in older patients with pre-existing vascular disease and when these concentrates are given at very high doses.[122,123] These products may be useful in selected patients without pre-existing hypercoagulable states at doses less than 30 IU/kg.[118] Bleeding from minor procedures such as dental extraction can be controlled with local measures or antifibrinolytic agents (aminocaproic acid and tranexamic acid) at the same doses that are used for hemophilia and vWD.[118]

Contact Factor Deficiencies

Deficiencies of the contact factors—FXII, prekallikrein, and high-molecular-weight kininogen—are not associated with bleeding symptoms.[104] Because these factors are necessary for the initiation of the intrinsic pathway, the PTT is markedly prolonged, frequently beyond what is seen in hemophilia, whereas the PT is normal. Both FXII and prekallikrein deficiencies are inherited as autosomal recessive traits.[104] Patients are usually identified during routine preoperative screening, and definitive diagnosis is made with specific contact factor assays. Treatment is not necessary.

Factor XIII Deficiency

Factor XIII deficiency is an autosomal recessive disorder. FXIII is also known as *fibrin-stabilizing factor* and is responsible for crosslinking of the fibrin polymer. Deficiency of FXIII is associated with reduced clot stability, and therefore ecchymoses or hematomas are usually seen 24 to 36 hours after trauma. FXIII deficiency is associated with severe bleeding, particularly delayed intracranial hemorrhage with minimal trauma. Other symptoms of FXIII deficiency include delayed separation of the umbilical stump in the neonatal period (at more than 3.5 to 4 weeks), poor wound healing, and recurrent spontaneous abortions in women secondary to severe decidual bleeding. Screening tests are normal, including bleeding time, PT, PTT, and thrombin time. Clots from affected persons appear more friable than normal. When the condition is suspected clinically, diagnosis of homozygous patients is made using a urea clot solubility assay or by measuring plasma levels of FXIII subunit proteins.[124]

Fresh frozen plasma is usually used for hemostasis in FXIII deficiency.[109] It is given at a dose of 5 to 10 mL/kg. Because the half-life of FXIII is very long (3 to 6 days), one dose is generally sufficient. Cryoprecipitate also contains FXIII and can also be used to treat acute bleeding episodes.[109] Patients with severe bleeding symptoms can receive either product as prophylaxis every 2 to 4 weeks. In addition, two plasma-derived FXIII concentrates are currently produced (by Centeon in the United States and Bio Products Laboratory in the UK).[125] These are not yet available for general distribution in the United States.

CONCLUSION

Accurate and early diagnosis, comprehensive clinical care, and the availability of factor concentrates that are manufactured with limited risk of transmitting blood-borne viruses and minimal risk of thrombosis have all contributed to improved outcomes for patients with congenital bleeding disorders. Despite these advances, patients with severe hemophilia require tremendous dedication and support to successfully manage their disease. The promise of gene transfer, which could allow for amelioration or elimination of the phenotypic abnormalities seen in severe hemophilia, is still in the future.

Chapter 35

Transfusion of the Patient with Acquired Coagulation Defects

Barbara Alving*

Patients who develop bleeding disorders because of underlying systemic disease, autoantibody formation, or as a result of complications of anticoagulant use can be effectively treated with strategies that may include, in addition to blood products, one or more hemostatic agents as well as newer immunosuppressive agents. This chapter discusses the diagnosis and treatment of the following acquired coagulopathies: those related to underlying systemic disorders such as liver disease and renal failure; disseminated intravascular coagulation (DIC); formation of autoantibodies to coagulation factors VIII, V, II, or XIII; and coagulopathies associated with anticoagulants and the newer antiplatelet agents.

APPROACH TO THE PATIENT WITH A COAGULOPATHY

Patient Evaluation

The evaluation of the patient with an apparent or possible coagulopathy includes a review of the past and present illness as well as use of medications and a physical examination. Patients who have developed autoantibodies to a clotting factor such as factor VIII may have no complaints other than easy bruising or unexpected excessive bleeding with minor trauma. For these patients, laboratory data may be the first indication of the etiology of a bleeding disorder.

Screening tests are an integral part of the initial evaluation (Table 35–1). If the activated partial thromboplastin time (aPTT) and prothrombin time (PT) are prolonged, then performing mixing studies to assess for the presence of an inhibitor and measuring coagulation factor levels are appropriate. If DIC is suspected, the levels of D-dimer, a late plasmin digest of crosslinked fibrin, should also be measured. Increased levels indicate that thrombin has been generated in sufficient quantities to activate factor XIII, which induces crosslinking of fibrin, and that plasmin has also been generated to degrade the fibrin. This process is consistent with the generalized activation of the coagulation and fibrinolytic system that occurs in DIC.

The complete blood count, along with evaluation of the peripheral smear, may reinforce the possibility of sepsis (e.g., toxic granulations and Döhle bodies in the neutrophils) and also help to determine whether or not an apparent thrombocytopenia is real or due to platelet clumping in ethylenediaminetetraacetic acid (EDTA).

Hemostatic Support, Including Blood Products

In the surgical setting, a realistic goal is to provide sufficient hemostatic support to allow the patient to undergo surgery or other invasive procedures without undue risk. Thus, complete correction of coagulation laboratory abnormalities may not be possible or even desirable. For example, replacement of factor VII, which has a half-life of 2 to 6 hours, by infusion of plasma could lead to excessive volume expansion and pulmonary edema.

A critical factor for patients who require invasive procedures such as line placement is the skill of the operator. In one retrospective review of patients who had received arterial, pulmonary artery, or central venous lines, the authors found that hemostatic complications were rare and were related more to the experience of the operator than to the underlying hemostatic defect.[1] They concluded that only patients with severe hemostatic defects require correction of the abnormalities before line placement.

For major surgery in patients with coagulopathies, hemostasis is best managed if there is close communication among the consultants, the surgeons, the personnel of the coagulation laboratory, and the staff of the blood bank (or pharmacy) who are responsible for supplying the products.[2] Examples of two newer products that are being used to provide hemostasis in a wide variety of clinical settings are fibrin sealant and recombinant factor VIIa (rFVIIa).

Products, such as fibrin sealant, that provide localized hemostasis can be used as adjuvants for systemic therapy in patients with coagulopathies. In the United States, one commercial product is now available (Tisseel). It is indicated for patients who are undergoing reoperative coronary artery bypass surgery or who have bleeding from sites, such as the spleen, where bleeding cannot be controlled by sutures. The product is composed of human fibrinogen (75 to 115 mg/mL) and human thrombin (500 IU/mL), both of which are virally inactivated.[3] The thrombin is solubilized in calcium chloride (40 mM), which stimulates crosslinking of the clot by factor XIII in the product (or patient). The product also contains aprotinin, a bovine-derived

All material in this chapter is in the public domain, with the exception of any borrowed figures or tables.

Table 35–1 Laboratory Testing for Patients with an Acquired Coagulopathy

Perform complete blood count, aPTT, PT, and thrombin time; measurement of fibrinogen concentration; and test for D-dimer as appropriate.
If thrombin time is prolonged, evaluate for heparin (perform reptilase time, add heparinase to sample). If heparin is present, check to be sure that the patient is not excessively anticoagulated or has developed a heparin-like inhibitor.
If aPTT is prolonged, perform "correction" studies. Mix equal volumes of patient and normal plasma and repeat the aPTT immediately and after 1 hour's incubation at 37° C. The values for the mixing study should be within 5 seconds of the control value of the normal plasma aPTT.
An aPTT that becomes more prolonged with incubation is suggestive of an inhibitor to a specific factor. An aPTT that is initially prolonged and remains prolonged to the same degree at 1 hour is suggestive of a lupus anticoagulant.
Measure factor levels to be sure that a true deficiency of a coagulation factor is recognized, even if the diagnosis is "lupus anticoagulant."
Consider the presence of an inhibitor to factor XIII if bleeding persists and the screening studies are normal. This requires a special test for the solubility of the clot in urea and monochloroacetic acid.

aPTT, activated partial thromboplastin time; PT, prothrombin time.

protein that directly inhibits plasmin, which is included to increase clot stability.

A much less expensive form of this product can be made by mixing cryoprecipitate in one syringe (fibrinogen concentration, 10 to 15 mg/mL) and bovine thrombin (1000 IU/mL) in the second syringe. However, this preparation contains a lower concentration of fibrinogen and has not undergone viral inactivation. Furthermore, the bovine thrombin may be contaminated with bovine factor V, which can stimulate production of antibodies in the recipient that crossreact with human factor V, inducing a potentially severe bleeding disorder several days after surgery.[4–6] Currently, the bovine thrombin preparation with the lowest degree of contamination with factor V is that produced for Jones Medical Industries, St. Louis.[7]

Efficacy data for the commercial fibrin sealant were derived in part from a study in which 333 patients from 11 centers in the United States who were undergoing reoperative cardiac surgery or emergency resternotomy were randomly assigned to receive fibrin sealant or conventional hemostatic agents; the end point for efficacy was the number of bleeding episodes controlled at 5 minutes.[8] The success rate for fibrin sealant was 92.6% compared with 12.4% for conventional topical agents ($p < 0.001$). Fibrin sealant also rapidly controlled bleeding episodes that did not initially respond to conventional hemostatic agents in 82% of patients.

In addition to use in cardiac surgery and trauma, fibrin sealants have been used as adhesives to seal dural leaks in neurosurgery, to promote union of middle ear bones in otolaryngology, and as a matrix to repair bone defects.[3] Although randomized, blinded studies have not been done, fibrin sealant has been applied to sites of dental extractions in individuals with hemophilia; this treatment, combined with the use of an antifibrinolytic agent, has reduced or eliminated the need for systemic factor VIII replacement.[9,10] This combined therapy would potentially be efficacious in patients with coagulation factor inhibitors as well as those with severe thrombocytopenia who require dental extraction. Outside the operating room, these sealants may also be applicable to providing local hemostasis in the critical care setting in patients with coagulopathies who have a localized site of bleeding. In a randomized, prospective evaluation of fibrin sealant in neonates undergoing extracorporeal membrane oxygenation, application of fibrin sealant at the cannulation sites reduced the risk for any bleeding and was associated with a shorter duration of hemorrhage with less blood loss.[11]

Fibrin sealants produced by several manufacturers (in both the United States and Europe) are undergoing or will be undergoing clinical trials in the United States. Differences may include methods of viral inactivation and presence or absence of a fibrinolytic inhibitor in the product. In addition, companies are developing other forms of sealants or adhesives composed of collagen and thrombin and devices that allow production of autologous fibrin sealant in the operating room.

Recombinant activated factor VII (rFVIIa, NovoSeven) is approved by the U.S. Food and Drug Administration (FDA) for use in individuals with hemophilia (factor VIII or IX deficiency) who have inhibitors and are actively bleeding or at high risk to bleed. During the past few years it has gained widespread use as a "universal hemostatic agent," although clinical trials to define the dose and efficacy in multiple situations have not yet been performed.

The "off-label" applications that are reported in the literature include treatment of bleeding episodes and/or prevention of bleeding related to surgery in patients with platelet disorders (qualitative and/or quantitative), liver disease (cirrhosis, transplantation), surgery and trauma, and reversal of warfarin therapy.[12–16] For patients with hemophilia who have inhibitors, the dose of rFVIIa is usually 90 µg/kg given every 2 hours (half-life, approximately 3 hours). The best doses to be used for continuous infusion are still being determined. For patients with factor VII deficiency, the most effective doses are 20 to 25 µg/kg. An international registry is being used to record experience on the doses used in patients with platelet disorders and hepatic failure as well as orthotopic liver transplantation.

In trauma and surgery, antecodotal reports suggest that in patients with excessive uncontrolled bleeding, one or two infusions of rFVIIa at doses ranging from 20 to 120 µg/kg can have a significant hemostatic effect.[12–16] The incidence of thrombosis has been estimated to be 1% to 2%.[14]

COAGULOPATHIES IN SYSTEMIC DISORDERS

Liver Disease

Pathophysiology and Laboratory Evaluation

Patients with liver disease may have a complex coagulopathy consisting of impaired coagulation factor synthesis,

increased fibrinolytic activity, and thrombocytopenia.[17] In patients with splenomegaly related to cirrhosis and portal hypertension, 90% of the circulating platelets can be sequestered in the spleen, with platelet counts decreasing to as low as 30,000 to 40,000/μL. The thrombocytopenia may be due in part to decreased platelet production because of reduced levels of circulating thrombopoietin, which is synthesized in the liver.[18] In one study of 44 patients with cirrhosis and thrombocytopenia, thrombopoietin levels were undetectable in 89%; however, after undergoing liver transplantation, 94% had detectable levels of thrombopoietin and all had resolution of the thrombocytopenia.[18] In patients undergoing portal decompression or splenectomy, thrombocytopenia often persists, indicating that a defect in thrombopoietin production is present in addition to splenic sequestration. A further reduction in platelet count is usually due to additional factors such as coexisting immune thrombocytopenia.[17] Patients may also have platelet dysfunction due to the effects of increased plasmin on platelet receptors. Increased levels of nitric oxide may also induce some degree of platelet dysfunction.[19]

The liver is the site of production for almost all coagulation factors, including the inhibitors protein C, protein S, and antithrombin. Von Willebrand factor (vWF) and tissue plasminogen activator (t-PA) are produced by endothelial cells. The factor VIII activity is usually increased in liver disease, which may reflect activation of the molecule or increased synthesis at sites other than the liver.[17] Factor VII, which has the shortest half-life of the coagulation factors (2 to 6 hours), is the first to be decreased in liver disease. To be functional, factors II, VII, IX, and X as well as protein S and protein C must undergo γ-carboxylation, which is mediated by vitamin K. However, liver disease causes impairment of γ-carboxylation that cannot be reversed with vitamin K1.[20]

Patients with liver disease, including those with hepatomas, may have an acquired dysfibrinogenemia caused by synthesis of a fibrinogen molecule that has impaired polymerization because of an increased sialic acid content.[21] The fibrinogen levels are usually normal; however, PT, aPTT, and thrombin time are prolonged. One case has been reported in which acquired dysfibrinogenemia was part of a paraneoplastic manifestation of renal cell carcinoma and resolved after the tumor was removed.[22] Acquired dysfibrinogenemia is not associated with a bleeding diathesis, and patients with this abnormality do not need any treatment before invasive procedures.

Although inhibitors of the coagulation system are decreased in patients with hepatic disease, a thrombotic state does not usually occur. Liver disease is associated with hyperfibrinolysis, as defined by increased activity of t-PA and elevation of D-dimer. In one study of cirrhotic patients, those with elevated t-PA and D-dimer had a significantly higher rate of gastrointestinal bleeding than those who did not have these laboratory findings.[23] Patients with ascites and hyperfibrinolysis were also at higher risk for bleeding than those without ascites. The authors postulated that hyperfibrinolysis results in part from activation of the coagulation system, resulting in release of t-PA in the presence of fibrin. Decreased clearance of t-PA as well as reduced levels of α_2-antiplasmin, which is synthesized in the liver and is the major inhibitor of plasmin, could result in continued plasmin generation and a bleeding diathesis.

The assessment of bleeding risk in a patient with liver disease includes measurement of the platelet count, PT, aPTT, fibrinogen level, and D-dimer. Although measurement of t-PA or the euglobulin clot lysis time is desirable, these tests are usually not available in a hospital setting. The PT is also reported as an International Normalized Ratio (INR), which was originally developed to standardize anticoagulation among patients taking warfarin. A study of 29 patients with liver impairment (INR, 1.5 to 3.5) was conducted with three different thromboplastin reagents (International Sensitivity Index, 0.86 to 2.53).[24] The mean INR for the patient plasmas as determined with the three different reagents ranged from 1.88 to 2.63, depending on the reagent. In contrast, the three reagents gave the same INR in plasmas from patients taking warfarin. Thus, INR values are not well standardized for patients with liver disease and can vary depending on the reagent. However, this is also true for the measurement of the PT with the different reagents. Patients with liver disease may have only a prolonged PT (normal aPTT and thrombin time), reflecting a decrease in factor VII, which is the first factor to be reduced in liver disorders because of its short half-life.

The bleeding time does not predict gastrointestinal bleeding in patients with cirrhosis.[25] Furthermore, mild to moderate coagulopathy is not associated with prolonged bleeding after liver biopsy, as assessed by measurement of the bleeding time at the biopsy site; even if the studies are normal, patients may still bleed at the biopsy site.[26] Although controlled studies in 21 patients with cirrhosis (platelet counts, 45,000 to 286,000/μL) have shown that desmopressin (DDAVP) at a dose of 0.3 μg/kg significantly shortens the prolonged bleeding time for up to 4 hours, its role in prophylaxis has not been well defined.[27] Nonetheless, DDAVP would be a reasonable choice for a hemostatic agent if there were concerns about platelet function.[27,28]

Product Support

Guidelines for prophylaxis in patients with liver disease who are undergoing invasive procedures are summarized in Table 35–2. These suggestions are empirical and are based on many factors. For example, in a retrospective study of patients undergoing percutaneous liver biopsy, McVay and Toy[29] found that mild elevations of PT or aPTT were not associated with bleeding. Risk factors for bleeding were malignancy (hepatoma) and multiple passes. These authors concluded that PT and aPTT prolonged to less than 1.5 times the midnormal range do not require treatment and that a platelet count above 50,000/μL is satisfactory.

For patients in whom standard percutaneous biopsy is contraindicated, such as those who have ascites, portal hypertension, and coagulopathy, laparoscopic liver biopsy can be performed successfully using direct pressure and topical Gelfoam and thrombin to achieve hemostasis.[30] In these patients there appears to be no correlation between the risk of bleeding and the prophylactic administration of fresh frozen plasma (FFP) or platelets. The advantage of laparoscopic liver biopsy is the ability to place direct pressure along with hemostatic agents.

There is usually little or no need to infuse FFP in an individual who has only a prolonged PT and a normal aPTT because factor VII levels of 10% or greater are sufficient for hemostasis. If PT and aPTT are prolonged and the patient has not responded to empirical treatment with vitamin K1 at a dose of 10 mg/day subcutaneously for 3 days,[17] measurement of levels of factors IX, X, and V (a non-vitamin K–dependent factor) provides a good assessment of liver function with respect to synthesis of coagulation factors. On occasion,

Table 35–2 **Management of Patients with Liver Disease**

Prophylaxis before Procedures	
Platelet count < 50,000/μL	Administer platelets to increase to 50,000–75,000/μL (six platelet concentrates or one apheresis platelet product)
Fibrinogen < 100 mg/dL	Administer cryoprecipitate to maintain fibrinogen > 100 mg/dL (7–10 units)
Coagulation Factor Deficiency	
Prolonged PT and aPTT	Administer vitamin K, 10 mg daily subcutaneously for 3 days, and then FFP if factor VII is <10% or other factors are >50%
Prolonged PT, normal aPTT	No treatment beyond vitamin K, if factor VII is >10%
Prolonged thrombin time (dysfibrinogenemia)	No treatment if fibrinogen > 100 mg/dL

aPTT, activated thromboplastin time; FFP, fresh frozen plasma; PT, prothrombin time.

abnormalities are simply due to dysfibrinogenemia, which can be detected by a prolonged thrombin time and reptilase time. If the latter is the case, no plasma treatment is needed.[22] Preoperative replacement for patients with severe factor VII deficiency consists of infusion of plasma at a dose of 5 to 10 mL/kg beginning preoperatively (in time to achieve a level of 10%) and continued during and after surgery for at least 1 to 2 days.

The Actively Bleeding Liver Disease Patient

Screening tests for a patient with liver disease who is actively bleeding consist of measurement of the platelet count, PT (INR)/aPTT, fibrinogen level, and D-dimer.[19] Even in the presence of laboratory abnormalities, the most frequently established causes for bleeding are site-specific tears in esophageal varices or gastrointestinal ulcers. Thus, sites for bleeding should be sought as well as establishment of an improved coagulation profile.

For patients who have hemostatic defects and are bleeding or are to undergo a major procedure, therapy does not have to be aimed at complete correction of laboratory values; however, the hematocrit should be maintained at greater than 30%, the platelet count greater than 50,000/μL, and the fibrinogen level greater than 100 mg/dL.

The best source of fibrinogen is cryoprecipitate, which contains approximately 250 mg in each bag. The volume of distribution for the fibrinogen is 30% greater than the intravascular volume. Thus, to increase the fibrinogen level by 50 mg/dL in a 70-kg individual, seven bags of cryoprecipitate would be required.

In patients undergoing rapid blood loss, rFVIIa can be combined with FFP. Factor VIIa has not been used extensively in patients with liver disease, and appropriate doses are being explored.[13–15] In one series of 10 consecutive patients with alcoholic cirrhosis and esophageal bleeding, infusion of rFVIIa (80 μg/kg) corrected the prolonged PT for 2 to 4 hours and controlled the bleeding; the clinical response lasted for at least 24 hours in half of the patients.[31] Prothrombin complex concentrates (PCCs) are not recommended, because they may be associated with thrombosis.[17] If a patient is oozing diffusely from sites of minor trauma and fibrinolysis is suspected, antifibrinolytic therapy can be tried after an initial evaluation for DIC and urinary tract bleeding. The antifibrinolytic agent aminocaproic acid can be given intravenously at doses of 4 to 5 grams over 1 hour followed by 1 g/hr for 8 hours. The oral dose is 4 g every 4 hours.[19] If tranexamic acid is given orally, the dose is 25 mg/kg every 6 to 8 hours. The intravenous dose is 10 mg/kg as a bolus and then 10 mg/kg administered over 6 to 8 hours.[19]

Uremia

One of the most common sources of bleeding in uremia is the gastrointestinal tract. Studies have shown, however, that the causes of gastrointestinal bleeding in patients with uremia are not different from the causes in those who are not uremic,[32] and the frequency of rebleeding is similar for both groups. The frequency of angiodysplasia may be twice as high in patients with renal failure compared to those without and may account for 19% to 32% of episodes of gastrointestinal bleeding in patients who have chronic renal insufficiency.[32] Patients who have occult gastrointestinal blood loss may develop iron deficiency and have a reduced response to erythropoietin. Thus, adequate attention should be given to iron replacement in an anemic patient who appears to be erythropoietin-resistant. Drugs such as low-dose aspirin may have a potentiating effect on the degree of bleeding.[19,33]

Patients who are uremic usually have a normal PT and aPTT and platelet count. However, they may have prolonged bleeding times; the degree of prolongation appears to correlate with clinical bleeding.[34] The platelet dysfunction has multiple causes, including exposure to increased levels of nitric oxide, which inhibit function.[33,35,36] In addition, platelets may have a storage pool defect, reduced production of prostaglandin, and decreased adhesion because of a decrease in expression of the receptor glycoprotein IIb/IIIa (GPIIb/IIIa), which is a binding site for vWF as well as fibrinogen.[37] The vessel wall in patients with uremia may produce an increased amount of prostaglandin I_2, which impairs platelet adhesion.[38] Plasma factors, not well characterized, may also inhibit platelet adhesion and aggregation in vivo.[39]

Multiple strategies can be used to reduce the excessive bleeding associated with uremia (Table 35–3). Platelet function can be maximized rheologically by maintaining the hematocrit at 30%.[40] The prolonged bleeding time can also be corrected by administration of DDAVP at a dose of 0.3 μg/kg intravenously or subcutaneously. The effect begins 1 hour after administration and persists for approximately 4 hours.[40,41] In uremic patients, the terminal half-life of DDAVP can range from 8 to 16 hours (mean, 9.7 hours).[42] Thus, clearance is decreased to 25% of that in individuals with normal renal function and the half-life prolonged 2 to 3 times. DDAVP should not be used more frequently than once in 24 hours; repeated doses are not efficacious and can result in hyponatremia and seizures. DDAVP works through release of presynthesized vWF from endothelial cells.

A double-blind, randomized trial of intravenous conjugated estrogens administered at a dose of 0.6 mg/kg/day for 5 days to six patients with uremia and prolonged bleeding

Table 35–3 **Hemostatic Options for Patients with Uremia**

Goal	Treatment	Comments
Maintain hematocrit 27%–32%	Erythropoietin	Monitor for hypertension; maintain adequate iron stores; check iron stores if patient resistant to erythropoietin.
Acutely enhance platelet function	DDAVP, 0.3 μg/kg IV	Administer no more frequently than once in 24 hours. Monitor for hyponatremia to avoid seizures.
Chronic enhancement of platelet function	Conjugated estrogens, 0.6 mg/kg/day IV for 4–5 days; or transdermal 17β-estradiol, 50–100 μg/24 hours applied as patch every 3–5 days for 2 months	Monitor for adverse effects: fluid retention, hot flashes.

DDAVP, desmopressin.

times found that the bleeding time was partially corrected by 6 to 48 hours after the first dose, with a peak effect at 5 to 7 days and a duration as long as 14 days.[43] Transdermal estrogen was efficacious in reducing or stopping bleeding in a series of six patients with renal failure, prolonged bleeding times, and excessive bleeding from telangiectasia of the gastrointestinal tract.[44] The estrogen was administered as 17β-estradiol (Estraderm) in a skin patch that delivered 50 or 100 μg/day. In these patients, the mean bleeding time decreased from 14 to 7 minutes. The effects were noted at 24 hours and persisted at 17 days (total duration of administration was 2 months). No adverse effects were noted.[44] Vigano and colleagues postulate that the prolonged effect of estrogens is due to their ability to enter endothelial cells, which are known to have estrogen receptors, and alter their function so that improved hemostasis occurs.[45] Other studies have shown that administration of estrogen inhibits endothelial nitric oxide production.[36]

In renal dialysis patients, graft thrombosis is a frequent event; secondary prevention includes administration of aspirin, warfarin, or heparin depending on the clinical situation; low-molecular-weight (LMW) heparin is not used because of its prolonged half-life in patients with renal failure.[46]

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation is associated with clinical conditions, such as sepsis, acute brain injury, or abruptio placentae, that induce expression of tissue factor and overwhelming activation of the coagulation system, with a resulting fibrinolytic response. The clinical manifestations of DIC are variable and depend on whether microvascular thrombosis with fibrin formation is the prominent feature or the major component is the fibrinolytic response to fibrin formation.[47] The clinical manifestations determine which hemostatic therapy, if any, is needed. In general, the most critical factor in the resolution of DIC is the ability to control the condition responsible for the initiation of the process.

The laboratory evaluation of DIC includes measurement of the platelet count, PT, aPTT, and D-dimer. An abnormality in any one of these tests is not specific for DIC. Rather, the test results are combined with the clinical setting to make a diagnosis. Serial coagulation tests are especially useful in establishing a diagnosis. If a patient is actively bleeding, blood products such as platelets, FFP, and cryoprecipitate may need to be administered. There is no evidence that administration of blood components increases the severity of the DIC.[47]

Sepsis

Thrombocytopenia may be a prominent aspect of sepsis and can be due to DIC or to hemophagocytosis.[48,49] Patients with hemophagocytosis also have elevated levels of ferritin and lactate dehydrogenase in addition to thrombocytopenia. The process resolves with treatment of the underlying condition.

Disseminated intravascular coagulation in sepsis is due in part to interleukin-6-induced expression of tissue factor, which generates procoagulant activity. The fibrinolytic response to fibrin formation is reduced because interleukin-6 also increases the expression of plasminogen activator inhibitor-1, the major inhibitor of t-PA. Thus, the major manifestation in sepsis may be microvascular fibrin deposition. The efficacy of heparin in this setting has not been demonstrated. Although administration of antithrombin III concentrates initially suggested promise in the treatment of sepsis, a phase III international trial of antithrombin III showed no effect on 28-day all-cause mortality in adult patients with severe sepsis and septic shock who received the concentrate within 6 hours of symptoms.[50]

Activated protein C (drotrecogin alfa [activated]) is approved for patients with severe sepsis; however, it does not appear to be beneficial in patients with severe sepsis who are at low risk for death.[51,52] In this population, it is associated with an increase in the rate of serious bleeding compared to placebo (2.4% vs 1.2%, $p = 0.02$).[51]

Acute Leukemia and DIC

Although DIC can be associated with any type of leukemia, it is most frequently associated with acute promyelocytic leukemia because the promyelocytes are rich in releasable tissue factor. The plasmin which is generated in DIC is initially inhibited by α_2-antiplasmin, its major inactivator.[47] However, with time, the α_2-antiplasmin is depleted, allowing plasmin activity to remain unchecked. This results in ongoing fibrinolysis and excessive bleeding.

The laboratory diagnosis of α_2-antiplasmin deficiency can be confirmed by a specific assay for α_2-antiplasmin that consists of measuring the rate at which plasmin added to patient plasma undergoes inhibition. Treatment is usually empiri-

cal and consists of administration of an antifibrinolytic agent such as oral aminocaproic acid or tranexamic acid.[53,54] Although the antifibrinolytic agents can be used alone, heparin is generally administered as an adjunctive agent at a dose of 300 to 500 U/hr to prevent continued generation of thrombin. A critical aspect of management of patients with acute promyelocytic leukemia is to maintain a platelet count of 50,000/μL or greater.

A combination of heparin and antifibrinolytic agents is also useful in patients with DIC related to solid tumors, such as prostatic carcinoma. Efficacy of treatment can be monitored clinically and by the increase in fibrinogen levels followed by an increase in platelets in 24 to 48 hours.

Obstetrical Conditions

Disseminated intravascular coagulation can occur with abruptio placentae, amniotic fluid embolism, retained placenta, preeclampsia, acute fatty liver, and in utero fetal death.[55] These processes are all associated with the release of tissue factor from the dead fetus or necrotic placenta. DIC is clinically noted by excessive or spontaneous bleeding combined with decreases in fibrinogen levels and platelet counts and increases in D-dimer.

The best treatment is to accomplish delivery as soon as possible. Blood products are given as needed until this can be achieved. The contraction of the myometrium and removal of the source of tissue factor are the two most important factors in controlling the DIC.[55] With proper treatment, the coagulopathy reverses in hours and no further treatment is required. The only obstetrical condition associated with DIC for which heparin has been efficacious is the rare condition in which fetal death has occurred in one of two or more fetuses carried by the mother. Full-dose intravenous heparin has been administered to allow the maturation and delivery of the other viable fetuses.[56,57]

AUTOANTIBODIES AGAINST COAGULATION FACTORS

Acquired antibodies to specific blood coagulation factors have been reported in association with a variety of conditions, including infections, malignancy, pregnancy, and autoimmune disorders.[58,59] The antibodies, which are usually of the immunoglobulin G (IgG) isotype, may not be detected until the patient undergoes a hemostatic challenge such as surgery, or they may develop in the postoperative period, causing increased morbidity and even mortality. Inhibitors should be suspected in patients who have sustained trauma or who have undergone a surgical procedure and yet continue to bleed excessively for no apparent reason. The first manifestation of an inhibitor may not be apparent for 4 to 5 days after surgery. A review of serial coagulation studies may show an increasingly prolonged aPTT or both PT and aPTT with no apparent explanation (i.e., not corrected by empirical use of vitamin K1 or FFP or, in the case of individuals with known hemophilia, decreased recovery immediately after infusion and shortened half-life of infused factor VIII). Evaluation of coagulation screening studies and measurement of appropriate factor levels can establish the diagnosis so that appropriate blood product replacement can be provided and immunosuppressive therapy initiated.

The antibodies most commonly associated with excessive bleeding are those that develop against factor VIII in a patient with or without hemophilia A. Postoperative patients may also develop an antibody against factor V, which may be due to exposure to bovine thrombin preparations that contain factor V. Patients may also develop lupus anticoagulants; in the critical care setting, these are usually IgM antibodies that are directed against phospholipid-binding proteins such as prothrombin. They are not associated with excessive bleeding unless the patient also has a true deficiency of prothrombin in association with the lupus anticoagulants. The essential goals for the successful treatment of patients with inhibitors are to establish the initial diagnosis and then plan for appropriate factor replacement as well as for immunosuppression to eliminate the inhibitor.

For patients who are not known to have hemophilia but who have a progressive prolongation of aPTT and continued or excessive bleeding with surgery, further evaluation should include a mixing study to test for the presence of an inhibitor and measurement of coagulation factors XII, XI, IX, and VIII. These tests can be followed by a Bethesda assay, which will provide an estimate of the inhibitor titer. The results are less accurate for those patients who have autoantibodies to factor VIII than for those who have alloantibodies (congenital hemophilia). One Bethesda unit (BU) is the reciprocal of the dilution of patient's plasma that destroys 50% of the factor VIII in normal plasma after incubation for 2 hours at 37° C. For example, a titer of 40 BU indicates that at a 1:40 dilution the patient's plasma can inhibit 50% of the factor VIII in normal plasma.

Factor VIII Deficiency

For patients who have hemophilia and known alloantibodies, exposure to factor VIII during the surgical procedure increases the antibody titer, resulting in a poor response to factor VIII by the fourth or fifth postoperative day. In these patients, serial aPTT and factor VIII measurements can be performed so that appropriate changes in therapy can be made if necessary. Depending on the clinical setting and the inhibitor titer, treatment choices include human factor VIII, rFVIIa, or activated PCCs.

Autoantibodies to factor VIII generally occur in individuals after age 50 and are first suspected when the patient presents with a complaint of new-onset bruising or bleeding into the soft tissues or from the gastrointestinal tract.[58] Associated conditions include rheumatoid arthritis, the postpartum period, allergies, asthma, autoimmune disorders, and malignancy; however, in approximately 50% of patients, no other medical disorders are identified.[58,59] In 1981, Green and Lechner[58] reported that major bleeding occurred in as many as 87% of patients with an acquired factor VIII antibody and resulted in death in 22%. With the advent of improved recognition and treatment of inhibitors, in terms of both treatment of bleeding episodes and use of immunosuppression, these data should now be improved.

Although antibodies to factor VIII can disappear spontaneously, the general approach is to begin immunosuppressive therapy to increase the factor VIII level to normal levels. Several therapies have been used with different degrees of success. Green and coworkers[60] reported a response rate of 30% to oral prednisone alone at a dose of 1 mg/kg of body weight administered daily for 3 to 6 weeks. The responders tended to have lower Bethesda titers than nonresponders (median, 3 BU vs 50 BU), although responses did occur in three patients with titers of 33, 52, and 240 BU. They also concluded that

cyclophosphamide at an oral dose of 2 mg/kg daily is an efficacious therapy for patients who cannot tolerate prednisone.[60] In a follow-up publication, Green[61] reported an 80% response rate in 10 patients treated only with prednisone; their initial titers ranged from less than 1 BU to 27 BU. Patients who did not respond to steroids or had adverse effects all responded to single-agent cyclophosphamide.

In a report of nine consecutive patients (ages 50 to 79) with inhibitor titers ranging from 2.5 to 1040 BU, Shaffer and Phillips[62] described complete remission in 2 to 10 weeks with combined treatment with oral cyclophosphamide (100 to 200 mg/day) and prednisone (50 to 80 mg/day) with slow tapering of these doses when the inhibitor titer was no longer detectable. Cyclosporine has also been used successfully in a limited number of patients at a dose that provides therapeutic serum levels (150 to 350 ng/mL).[63]

The most promising treatment to eliminate factor VIII autoantibodies appears to be rituximab, a monoclonal antibody against CD20, which removes CD20+ B lymphocytes from the circulation. The dose generally used is 375 mg/m^2 IV every week for 4 weeks with or without prednisone.[64] This treatment may reduce the duration of exposure to cytotoxic treatment for these patients. Based on their experience in a limited case series, Aggarwal and colleagues have suggested a treatment algorithm for older patients with autoimmune hemophilia.[64] They recommend prednisone alone for those with a Bethesda titer of <5BU, and addition of rituximab to prednisone for those with low to intermediate titers (<30 BU). For those with higher titers, a combination of prednisone, cyclophosphamide, and rituximab may be required. Patients with very high titers may need to be treated with regimens that are used for chronic lymphocytic leukemia.[64]

A general approach to the use of coagulation factor components in patients with acquired factor VIII inhibitors is summarized in Table 35–4. For patients with an inhibitor titer that is less than 5 BU, factor VIII concentrates can still be used to neutralize the antibody and achieve a hemostatic level of factor VIII.[65] For those with a higher titer, other options exist, such as activated PCCs (Feiba and Autoplex T) and rFVIIa. In the United States, rFVIIa has largely replaced the use of PCCs.

In a retrospective French study of use of Feiba in 60 patients with inhibitors (most of whom had congenital hemophilia), efficacy was rated as excellent in 81% of bleeding episodes, which included surgical procedures, and poor in 17%.[66] The treatment was well tolerated in 98% of episodes; the doses infused were 65 to 100 U/kg at 6- to 12-hour intervals (total, 65 to 510 U/kg/day).

In patients with high-titer inhibitors, rFVIIa has been efficacious at a dose of 90 μg/kg administered intravenously every 2 hours during surgery and for 48 hours postoperatively, followed by every 2 to 6 hours for the next 3 days.[67] Factor VIIa has also been tested for home use in the treatment of mild to moderately severe bleeding episodes in the joints, muscles, or mucocutaneous tissues in patients with hemophilia A or B with inhibitors.[68] In this study, patients received rFVIIa (90 μg/kg) intravenously at 3-hour intervals within 8 hours of the onset of the episode. If the dose was considered effective after one to three applications, one additional injection was provided. rFVIIa was considered effective in 92% of bleeding episodes after a mean of 2.2 injections. The time from onset of bleeding to the first injection in the successfully treated episodes was 1.1±2.0 hours (standard deviation).

Several papers have described the use of sequential or alternative doses of activated PCCs and rFVIIa in patients with hemophilia and inhibitors who were actively bleeding.[69,70] Activated PCCs have been given in doses ranging from 35 to 80 U/kg alternating every 6 hours with rFVIIa (80 to 225 μg/kg).[69] If sequential therapy is to be undertaken, the patients should undergo serial laboratory monitoring for DIC. Additional studies need to be done to confirm the safety and efficacy of this treatment.

Factor V Deficiency

Antibodies to factor V are rare and are first manifested clinically as unexpected bleeding or bruising in a patient with a prolonged PT and aPTT. Multiple reports have described postoperative patients who have experienced significant bleeding related to factor V antibodies.[4–7] The coagulopathy develops as a result of exposure of the patient to bovine thrombin during surgery. Bovine thrombin, which is a commonly used hemostatic agent, contains multiple impurities, including bovine factor V. Patients develop antibodies to the bovine factor V, which then crossreact with their endogenous factor V, causing a marked inhibition of factor V activity.[5] Patients may also develop antibodies to the bovine thrombin. However, these antibodies do not crossreact with human thrombin and are of no clinical significance.

Patients who have antibodies to factor V have a prolonged PT and aPTT that are not corrected when the tests are repeated with a 1:1 mix of normal and patient's plasma. The prolongation of the PT and aPTT becomes even greater when the tests are repeated after incubation of patient's and normal plasma for 1 or 2 hours at 37°C. Measurement of

Table 35–4 Treatment of Bleeding Episodes in Patients with Inhibitors to Factor VIII

If Bethesda titer is <5 BU, use recombinant factor VIII concentrates; monitor factor VIII activity. Because Bethesda titers are not highly accurate in nonhemophiliac patients with an inhibitor, recombinant factor VIII may also be effective if the titer is >5 BU. The factor VIII activity is the best guide for treatment. An initial high dose may be required to neutralize the inhibitor in vivo, and then lesser doses may provide satisfactory activity. If possible, factor VIII should be the first choice for treatment.
Recombinant factor VIIa can be used at a dose of 90 μg/kg every 2 hours for the duration of bleeding and for several days thereafter. Choice of recombinant factor VIIa over activated prothrombin complex concentrates may be based on experience of the physician, cost, and availability. The two treatments have not been directly compared. Disadvantage of the activated prothrombin complex concentrates is potential for inducing thrombosis.
Activated prothrombin complex concentrates (Feiba 75–100 U/kg every 8–12 hours or Autoplex 50–75 U/kg every 8–12 hours) can be used for soft tissue bleeds and other bleeding episodes. Efficacy is judged by patient's response. For soft tissue bleeds, patients can be treated every 8 hours for 48 hours followed by every 12 hours for the next 48 hours.

coagulation factors shows a decrease in factor V. An antibody to bovine thrombin is detected by a prolongation of the thrombin time if bovine thrombin is used in the test system. The test remains abnormal when repeated with a 1:1 mix of normal and patient's plasma. The thrombin time is normal, however, if human thrombin is used in the test system.

The majority of patients in whom an antibody to factor V develops do not have clinical symptoms and the PT and aPTT become normal within 3 to 6 weeks after exposure to thrombin. For patients who are actively bleeding, FFP is the first choice for replacement of factor V. Infusion of platelets is a second option because they contain approximately 20% of the body stores of factor V, although they may not provide hemostasis in all situations.[71] Treatment with rFVIIa may also be an option for these patients.

Corticosteroids, cyclophosphamide, and vincristine have been used alone or in combination for suppression of antibodies. Corticosteroids have mostly been used alone as first-line therapy with success. Methylprednisolone at an initial dose of 1 to 1.5 mg/kg is usually given for 2 to 3 weeks and then tapered slowly over the next several weeks.[7] Cyclophosphamide and vincristine have been added to prednisone to suppress the antibody production successfully in cases with acquired factor VIII inhibitors; similar success has been achieved in some cases with factor V inhibitors. The use of rituximab has not been described in this clinical setting.

Factor II Deficiency

Autoantibodies to prothrombin usually occur in association with lupus anticoagulants, which are antibodies to phospholipid-binding proteins such as prothrombin or β_2-glycoprotein I.[72] Lupus anticoagulants are associated with the antiphospholipid syndrome, systemic lupus erythematosus (SLE), and infections as well as use of medications, such as procainamide (Pronestyl). In some patients with lupus anticoagulants, a true deficiency of prothrombin has also been recognized; this appears to be due to IgG antibodies that selectively bind prothrombin without neutralizing its activity. The antibodies do not interfere with the proteolytic cleavage of prothrombin or with the activity of thrombin. They appear to induce true prothrombin deficiency by binding to prothrombin in vivo and causing increased clearance.[73–75]

The majority of patients with lupus anticoagulants and SLE or other autoimmune connective tissue disorders may have IgG autoantibodies to prothrombin, although only 30% of patients with antibodies have a detectable prothrombin deficiency.[72] Antiprothrombin antibodies are more likely to occur in patients with an aPTT that is significantly prolonged (at least 50 seconds; normal range, 22 to 30 seconds).[74] Bleeding symptoms are correlated with the level of functional prothrombin and occur in patients with a prothrombin activity of 10% or lower.[74] In some cases, the first manifestation of lupus is the development of a lupus anticoagulant with true prothrombin deficiency. A significant decrease in the prothrombin activity related to antibody formation can occur at any time in a patient who has a lupus anticoagulants and underlying SLE or primary antiphospholipid syndrome. For patients with a lupus anticoagulants who are receiving warfarin, the first manifestation of an antibody to prothrombin that induces a significant decrease in the prothrombin activity may be a gradually increasing INR with no other apparent etiology.

Lupus anticoagulants and clinically significant hypoprothrombinemia have been associated with viral illnesses in children.[76] In these cases, the antibody disappeared spontaneously. The antibody production can usually be suppressed by administration of corticosteroids with or without adjunctive agents such as azathioprine; with this treatment, the PT can become normal as soon as 7 days after initiation of treatment.[73,75] For example, a 3-year-old girl with a viral illness and severe hypoprothrombinemia that resulted in epistaxis and gastrointestinal hemorrhage was treated successfully with intravenous methylprednisolone daily for 3 days followed by oral prednisone.[77] For a patient who is actively bleeding and has a severe prothrombin deficiency, treatment options are FFP or PCCs. Although not reported, rFVIIa could also be used.

Factor XIII Deficiency

Factor XIII deficiency may be due to the formation of autoantibodies that occur spontaneously or in association with drugs such as penicillin, isoniazid, or diphenylhydantoin or with autoimmune disorders.[78,79] The inhibitor is not detected on routine screening tests and can be confirmed only by finding rapid lysis of a clot that has been prepared from recalcified plasma and placed in 1% monochloroacetic acid or urea. Treatment consists of immunosuppressive agents and administration of cryoprecipitate if the patient is actively bleeding.

Laboratory monitoring of therapy can be done serially and qualitatively by assessing the time required for solubilization of a clot derived from patient plasma in urea or monochloroacetic acid.[80,81] Successful immunosuppression with rituximab has been reported in one patient with an apparent ciprofloxacin-induced antibody.[82]

COAGULOPATHIES RELATED TO ANTICOAGULANT ADMINISTRATION

Warfarin

The frequency of bleeding in patients who are receiving warfarin ranges from 8 to 16 per hundred patient-years, with major bleeding occurring in 1.3 to 2.7 patients per hundred years.[83] Patients at increased risk for bleeding are the elderly; those who have comorbid conditions such as cardiac, cerebrovascular, renal or hepatic disease; and those who have just recently been started on warfarin therapy or who have increased or fluctuating INRs.[84] One of the most important factors that predicts the risk for major bleed is a history of bleeding, especially if the site is in the gastrointestinal tract.[85]

Maintenance daily doses of warfarin can range from 4 mg up to 90 mg or higher in rare circumstances. Overall, more than 40% of the variability in warfarin dose requirements may be explained by genetic factors, use of concomitant specific medications such as amiodarone, age, and body surface area.[86] Two examples of the influence of genetic variation affecting dose requirements are related to the polymorphisms in the gene that codes for the cytochrome P450 complex *(CYP),* which is responsible for metabolizing the potent "S" form of warfarin. Individuals who have polymorphisms in the *CYP2C9* gene, which produces the protein that metabolizes "S" warfarin, may have reduced catabolism of the "S"

form and therefore have greatly reduced dose requirements.[86] Another genetic determinant of warfarin requirement is due to polymorphisms in the vitamin K epoxide reductase complex subunit 1 *(VKORC1)* gene, which affects the activity of vitamin K epoxide reductase complex. This complex, which is the target of warfarin, is responsible for regenerating reduced vitamin K so that it can serve as a cofactor for γ-carboxylation of coagulation factors. Polymorphisms in the gene can confer marked resistance or increased sensitivity to warfarin.[87]

The main strategies for treating warfarin overdose, depending on the degree of overanticoagulation and the clinical site of bleeding, include administration of vitamin K1, rFVIIa, PCCs, or FFP if the other products are not available (Table 35–5).[85] PCCs, which contain factors II, VII, and X in addition to factor IX and are virally inactivated, were originally developed for treatment of individuals with hemophilia B. Although PCCs are no longer used for this purpose, they are effective for use in the emergency correction of coagulation factor deficiencies in individuals who have major bleeding and are anticoagulated with warfarin.[88]

Approximately 50% to 90% of intracranial hemorrhages in patients receiving warfarin anticoagulation occur at a time when the INR is within the target range.[84] The mortality associated with intracranial bleeding is 16% to 68% and is influenced by the rapidity with which normalization of the coagulation factor deficiencies occurs.

The preferred replacement therapy in intracranial hemorrhage is rFVIIa or PCCs (25 to 50 U/kg). When PCCs were compared with infusion of 800 mL of FFP in a small study of patients with intracranial hemorrhage who were also anticoagulated with warfarin, the coagulation factor levels were raised into the normal range with the PCCs but not with FFP.[84] The INR can be corrected four to five times more quickly with the PCCs than with FFP. The elimination half-lives of the coagulation factors are as follows: factor II (58 hours), factor VII (5 hours), factor IX (19 hours), and factor X (35 hours); thus, repeated infusion may be necessary if the factor deficiency has not been reversed in 24 hours by the administration of vitamin K. Factor VII is in low concentration in some PCCs relative to the other coagulation factors, and it has a short half-life. The importance of replacing the factor VII level to values greater than 10% is unknown. FFP can be used to achieve minimal levels of 10% if this is deemed necessary. For some patients, especially those with mechanical heart valves, resuming anticoagulant therapy is critical; one report of 15 patients showed that this could be done safely.[89]

In a prospective case series, Deveras and Kessler administered rFVIIa to 13 patients (some of whom were actively bleeding) who needed rapid reversal of excessive warfarin anticoagulation.[90] rFVIIa was effective in doses ranging from 15 to 20 μg/kg. The cost of the product was approximately $1.40/μg at the time of this study. The product initially was administered at a dose as high as 90 μg/kg; however, lower doses were found to be effective. None of the patients sustained any adverse side effects from rVIIa. The INR value does not reflect the efficacy of the treatment; rather, patients who receive rFVIIa need to be clinically evaluated.

For patients who have ingested rat poison containing a superwarfarin such as brodifacoum, prolonged treatment with daily oral vitamin K is needed because the half-life of the superwarfarin is 16 to 36 days.[91] Oral vitamin K has a bioavailability of 10% to 60% and is therefore given at a dose three to five times greater than the parenteral dose. Initially, oral vitamin K may have to be taken every 6 to 8 hours and then tapered to a daily dose.

Heparin Preparations (Unfractionated Heparin, LMW Heparin, and Pentasaccharide)

According to one study, risk factors for bleeding are the same for patients receiving unfractionated heparin or LMW heparin and include the performance status of the patient as determined by World Health Organization criteria, history of a bleeding tendency, cardiopulmonary resuscitation, recent trauma or surgery, body surface area, and total dose of anticoagulant administered in 24 hours.[92] The bleeding risk may also be increased in older patients (>70 years).[93,94]

For unfractionated heparin, reversal of anticoagulant activity can be achieved by slow infusion (over 10 minutes) of protamine sulfate, which neutralizes 100 units of heparin for every milligram of protamine administered. Assuming that heparin has a half-life of 60 minutes, the protamine dose can be calculated in a patient receiving a constant IV infusion by adding the heparin dose infused during each of the past 3 hours.[95] The risk for anaphylaxis with protamine sulfate is approximately 1% and may be higher in diabetics who have taken NPH insulin or in patients who have allergies to fish or have undergone a vasectomy. Patients at risk for anaphylaxis should be pretreated with corticosteroids and with antihistamines.[96] For LMW heparin, protamine neutralizes only about 60% of the anti-factor Xa activity. If LMW heparin is administered within 2 hours of the bleeding episode, then protamine can be given based on a calculated dose of 1 mg for every 100 anti-factor Xa units given. This can be repeated at half the dose if bleeding continues.

Table 35–5 **Guidelines for Reversal of Warfarin Anticoagulation***

Major bleeding	Stop warfarin Infuse rFVIIa or PCC (50 U/kg) or FFP (15 mL/kg) if rFVIIa or PCCs are not available Give vitamin K1 10 mg by slow IV infusion
INR > 9 (with no or minor bleeding)	Stop warfarin Restart when INR therapeutic Give vitamin K1 5–10 mg orally

FFP, fresh frozen plasma; PCC, prothrombin complex concentrates.

Adapted from Ansell J, Hirsh J. Poller L, et al. The pharmacology and management of the vitamin K antagonists. The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. Chest 2004;126:204S–233S (www.chestjournal.org).

The role of rFVIIa in reducing bleeding in this setting has not yet been clearly defined.[96] However, one preliminary report describes the use of rFVIIa in three patients with hypercoagulability who were anticoagulated with enoxaparin and were bleeding from the site of a kidney biopsy, femoral pseudoaneurysm, and arthroplasty, respectively.[16] The patients each received rFVIIa as a single infusion in doses that ranged from 20 to 30 μg/kg. All patients had required multiple infusions of FFP and packed red blood cells before administration of rFVIIa.

LMW heparin, when administered subcutaneously, has a plasma half-life of 3 to 6 hours. Since the approval of enoxaparin (Lovenox) in 1993 for prophylaxis after total hip or knee replacement at a dose of 30 mg subcutaneously every 12 hours, the FDA has received reports of more than 30 patients who experienced spinal or epidural hematomas in conjunction with LMW heparin prophylaxis and spinal or epidural anesthesia. The mean age of the patients was 74 years, and 75% were women. The procedures were predominantly orthopedic (hip or knee replacement), and more than 80% of the patients were receiving LMW heparin twice daily. Published guidelines have emphasized that in patients receiving LMW heparin preoperatively, needle placement for epidural or spinal anesthesia should occur no sooner than 12 hours after the last dose.[97–99] Subsequent dosing should be delayed for at least 2 hours after needle placement. Epidural catheters should be removed 12 to 24 hours after the last LMW heparin dose, with subsequent dosing delayed by at least 2 hours.[97,98] In addition, enoxaparin should be used whenever possible as a once-daily dose,[99] and other antiplatelet or anticoagulant agents should not be administered at the same time.

Fondaparinux (Arixtra) is a synthetic heparin pentasaccharide that inhibits factor Xa through its action on antithrombin; it does not inhibit thrombin, however.[100] In the United States, fondaparinux has been approved for the prevention of postoperative deep venous thrombosis. It has a half-life of 18 hours, allowing it to be administered subcutaneously once daily. Because it is excreted renally, it is contraindicated in patients with renal insufficiency. Recent studies, both in vitro and in vivo, have provided evidence that fondaparinux can be used in patients with heparin-induced thrombocytopenia (HIT), since it does not interact with platelet factor 4. Abstracts and case series have reported a normalization of platelet counts and no complications of bleeding or thrombosis in patients with HIT who received fondaparinux (generally at a dose of 2.5 mg daily).[101,102] There is no well-tested antidote for fondaparinux; however, one study in 16 normal volunteers who received fondaparinux (10 mg subcutaneously) followed 2 hours later by rFVIIa (90 μg/kg) reported normalization of thrombin generation for 2 to 6 hours after rFVIIa administration.[103]

Thrombin Inhibitors (Lepirudin, Bivalirudin, and Argatroban)

Lepirudin (Refludan), which is a recombinant protein, is approved for use in patients with HIT and associated thrombosis to prevent further complications. In one study, patients with HIT received lepirudin at a dose of 0.4 mg/kg as a bolus followed by continuous infusion of 0.15 mg/kg/hr; if they had received thrombolytic therapy, the dose was decreased to 0.2 mg/kg (bolus) followed by 0.1 mg/kg/hr continuous infusion. For prophylaxis, they received a dose of 0.1 mg/kg/hr as a continuous infusion.[104] The treated patients were compared with historical controls; the combined end point of mortality, limb amputation, and new thromboembolic events was reduced by 50% ($p = 0.014$) at day 7 and at day 35 in the group receiving lepirudin. Bleeding events and transfusions were not increased in the treated group compared with the historical controls. Current dosing recommendations are 0.4 mg/kg as a bolus with 0.15 mg/kg/hr (up to weight of 110 kg). The dose can be monitored with the aPTT, and recommendations are to maintain the aPTT at 1.5 to 2.5 times the median value for the normal range.

In normal volunteers, lepirudin, which is excreted and perhaps metabolized by the kidneys, has a half-life of approximately 2 hours. Pharmacokinetic studies in patients with renal failure who were undergoing dialysis showed that after a single dose of lepirudin (0.08 to 0.2 mg/kg) followed by five additional dialyses without further dosing, the half-life was increased to 52 hours.[105] The distribution volume was also lower in hemodialysis patients than in normal volunteers. Lepirudin has been used successfully to maintain anticoagulation during dialysis when given once before dialysis at a dose of 0.08 mg/kg.[106] However, subsequent dosing would require adjustment because of the prolonged half-life. The manufacturer recommends that dosing be reduced by 50% for both bolus and infusion for patients with a creatinine value of 1.5 to 2.0 mg/dL. Reductions would be even greater for those with more severe renal impairment.

The use of lepirudin in five patients who required bypass surgery has also been reported.[107] In these patients the dose was monitored by a coagulation-based assay, and infusions were given to maintain the plasma levels above 2 μg/mL. In patients receiving lepirudin for deep venous thrombosis, the plasma level at steady state was approximately 0.6 μg/mL.[108] In one patient who experienced severe lepuridin-induced bleeding after bypass surgery, the infusion of rFVIIa at a dose of 60 μg/kg had a major hemostatic impact compared to previous infusions of packed red cells, platelets, and FFP.[109]

With time, patients can develop antilepirudin antibodies that cause a further prolongation of the aPTT. In this situation, the dose needs to be reduced.[110]

The thrombin inhibitor bivalirudin (Angiomax) is a peptide modeled after hirudin; bilvalirudin has a half-life of 25 minutes and undergoes minor renal metabolism (20%). It is approved in the United States for percutaneous coronary angioplasty but can also be used in patients with HIT and is undergoing testing in these patients in cardiac surgery.[110]

Argatroban, a thrombin-specific inhibitor that has been used in more than 300 patients with HIT, is an arginine-based synthetic molecule. Argatroban has a half-life of 40 minutes in normal individuals. Unlike lepirudin, argatroban does not require dose adjustment in patients with renal disease.[111] Argatroban, which is cleared by the liver, requires dose reduction in patients with significant hepatic dysfunction. It is administered in weight-based doses, adjusted to maintain the aPTT 1.5 to 3 times the baseline value. Argatroban has been used successfully in patients with HIT who required repeated dialysis[112] and in a patient with HIT and thrombosis who required coronary stent implantation.[113]

The thrombin-specific inhibitors, unlike unfractionated heparin, prolong the PT as well as the aPTT. In patients who are undergoing conversion to warfarin while receiving argatroban or hirudin, these agents can be discontinued several hours before a PT is determined to ensure an accurate indication of the INR.

Clinical experience with these agents in critically ill patients who are receiving multiple other drugs as well as anesthetic agents is limited and is not well described in the literature. Thus, dosing in critically ill patients should be established with caution. In a retrospective chart review of 65 patients admitted to a medical or surgical intensive care unit who received argatroban for more than 24 hours, the authors concluded that doses of argatroban that are only 50% of those recommended should be used in patients with acute renal failure, sepsis, or one organ system failure even if the alanine transaminase, bilirubin, and INR are normal.[114] They suggest that the metabolism of argatroban may be delayed in these patients due to passive hepatic congestion or due to the effects of other drugs.

BLEEDING INDUCED BY ANTIPLATELET AGENTS

Agents That Inhibit the Platelet GPIIb/IIIa Receptor (Abciximab, Tirofiban, and Eptifibatide)

The most potent antiplatelet agents in clinical practice today are those that block the interaction between fibrinogen and platelet glycoprotein IIb/IIIa (GPIIb/IIIa), thus mimicking the bleeding diathesis seen in patients with Glanzmann thrombasthenia. Abciximab (ReoPro) is a Fab fragment of chimeric human–murine monoclonal antibody c7E3, which is used in patients undergoing percutaneous transluminal angioplasty (PTCA) and those with unstable angina with PTCA planned in 24 hours.[115] Treatment of patients undergoing angioplasty or stent procedures with abciximab significantly reduced the combined end point of death, repeated myocardial infarction, and need for urgent revascularization during 30 days compared with those undergoing stent procedures in the absence of abciximab.[115] Two newer GPIIb/IIIa inhibitors have also been licensed. One is tirofiban (Aggrastat), a tyrosine derivative that is indicated for patients with unstable angina or non–Q wave myocardial infarction (with or without PTCA).[116,117] The other is eptifibatide (Integrelin), a cyclic heptapeptide that is indicated for patients with unstable angina or non–Q wave myocardial infarction (with or without PTCA) and for patients undergoing PTCA.[118]

The risk for bleeding with these agents is in part due to their pharmacokinetics. Abciximab, which has a high affinity for GPIIb/IIIa, has a biologic half-life of 8 hours; in comparison, 1 hour after completion of the infusion of eptifibatide, the bleeding time becomes normal.[119] The antiplatelet effect of tirofiban is also short-lived after completion of infusion, although in patients with renal failure the biologic effect is more prolonged. Platelet function is inhibited when more than 80% of the GPIIb/IIIa receptors are blocked. For patients who are bleeding, the drugs should be discontinued immediately and 8 to 10 units of platelet concentrates (or one apheresis platelet unit) administered. The drug redistributes to the receptors of the infused platelets, thus lowering the occupancy of the receptors of the entire platelet pool and resulting in normalization of platelet function.

In patients who have received abciximab within 12 hours of requiring an emergent bypass procedure, platelet infusions should be administered prophylactically to prevent excessive bleeding.[120] This recommendation is based on the observation that patients who underwent bypass surgery within 12 hours of abciximab experienced threefold greater blood loss than those who underwent surgery more than 12 hours after receiving the drug (1300 vs 400 mL, respectively).[121] These patients required platelet infusions, red blood cells, and FFP. The recommendation for preoperative platelet infusions probably does not apply for tirofiban or eptifibatide because of their shorter duration of action.

The GPIIb/IIIa inhibitors can cause an acute thrombocytopenia that occurs as soon as several hours after the initiation of drug infusion.[122] For patients receiving abciximab, the incidence may be as high as 1% with the first exposure to the drug and 4% on repeat exposure.[123] The incidence of thrombocytopenia with administration of tirofiban and eptifibatide has not been well defined. The platelet counts for patients who are to receive the GPIIb/IIIa inhibitors should be measured before the infusion and within 2 to 6 hours after infusion.[122,124] If the platelet count is reduced, the peripheral blood smear should be checked to rule out pseudothrombocytopenia due to platelet agglutination occuring in the presence of EDTA. True thrombocytopenia is due to preformed antibodies that are directed against the GPIIb/IIa receptor in the presence of the GPIIb/IIIa inhibitors. The treatment for a bleeding episode is infusion of platelets, regardless of the platelet count. The drug will be redistributed among the receptors of the infused platelets and circulating platelets, thereby allowing normalization of platelet function if receptor occupancy on the platelets is less than 80%.

Agents That Inhibit the Platelet ADP Receptor (Clopidogrel and Ticlopidine)

The thienopyridines ticlopidine and clopidogrel inhibit platelet function by blocking the adenosine diphosphate (ADP) receptor.[125] Although ticlopidine has been widely employed to prevent stent closure after angioplasty and as secondary prevention against stroke in patients with cerebrovascular disease, its relatively poor safety profile has resulted in diminished use. Adverse events in patients receiving ticlopidine have included neutropenia, agranulocytosis, aplastic anemia, and thrombotic thrombocytopenic purpura.[126] In contrast, clopidogrel appears to have an excellent safety profile.

In a large, randomized, blinded trial in patients with atherosclerotic vascular disease, clopidogrel reduced the combined risk of ischemic stroke, myocardial infarction, and vascular death by 8.7% compared with aspirin ($p < 0.05$).[127] Patients treated with clopidogrel had fewer gastrointestinal ulcers and fewer gastrointestinal bleeding episodes than those treated with aspirin. Clopidogrel is indicated for the reduction of atherosclerotic events (myocardial infarction, stroke, and vascular death) in patients with atherosclerosis documented by recent stroke, myocardial infarction, or peripheral vascular disease.

Both clopidogrel and ticlopidine require metabolism by the hepatic cytochrome P450-1A enzyme system to acquire activity.[125] When clopidogrel was given at a dose of 300 to 400 mg orally, it caused maximal inhibition of platelet function within 2 hours.[128] With a daily dose of 75 mg, the same degree of inhibition was achieved at 3 to 7 days. Recovery of platelet function occurs over 3 to 5 days after discontinuation of either drug. Specific treatment for bleeding related to these agents is not well described. Administration of desmopressin, however, may shorten the bleeding time and provide temporary hemostasis.[129] Otherwise, supportive care

and infusion of platelets may be needed in patients who are taking clopidogrel or ticlopidine and have a major bleeding episode.

SUMMARY

Acquired coagulation disorders range from subtle to catastrophic. Most can be quickly diagnosed by the history and appropriate laboratory testing, which is usually available in a tertiary hospital. Measurement of specific coagulation factors is much more useful than random infusion of FFP. A major problem is having the appropriate blood components available for the patient. If a hospital does not routinely stock coagulation factor concentrates, the patient should be transferred to a hospital where the specialty care can be provided; in addition, the hospital should know how to arrange for a core of specialty products that may be required on an emergent basis. The appropriate use of the newer products, such as rFVIIa, is still under investigation; cost and availability are two concerns for many hospitals. Because multiple options are available for the treatment of patients with acquired bleeding disorders, communication and collaboration among the services involved in the diagnosis and management of these patients will maximize the potential for good outcomes.

Chapter 36

Obstetric and Intrauterine Transfusion

Jeannie Callum • Jon Barrett

INTRODUCTION

Transfusion care of the pregnant woman and fetus can be extremely challenging despite the rarity of its occurrence. Pregnant women and fetuses require special considerations and properly selected blood components for transfusion. In this chapter five core aspects of obstetric and intrauterine transfusion will be reviewed, including the management and prevention of postpartum hemorrhage, prevention of RhD alloimmunization, monitoring of the severity of alloimmunization, management of alloimmunization, and neonatal alloimmune thrombocytopenia.

POSTPARTUM HEMORRHAGE

Definition

Postpartum hemorrhage can threaten the life of a healthy woman undergoing an otherwise uncomplicated vaginal delivery. It is the ultimate test of the obstetrical, anesthesia, nursing, and transfusion services. Processes should be in place in every obstetrical unit to clearly delineate the management of these women. Primary hemorrhage in the obstetric patient can be defined as any of the following within 24 hours of delivery: estimated blood loss greater than 1500 mL, 40 g/L or greater drop in the hemoglobin level, or the transfusion of 4 or more units of red blood cells.[1] Other definitions for postpartum hemorrhage have been proposed. A common definition is blood loss in excess of 500 mL after vaginal birth or greater than 1000 mL after cesarean section. The difficulty with the latter definition is illustrated by studies assessing blood loss in the postpartum period, showing that mean blood loss after vaginal and cesarean deliveries is approximately 500 mL and 1000 mL, respectively.[2,3] Clearly, the first definition more accurately identifies patients with a significant postpartum hemorrhage who are at risk for transfusion.

Incidence and Etiology

Postpartum hemorrhage is a leading cause of death in the pregnant patient worldwide, including the United States,[4] United Kingdom,[5] and France.[6] It is estimated that 125,000 women worldwide die of postpartum hemorrhage each year.[7] Causes of postpartum hemorrhage include placenta previa, uterine atony, retained placental tissue, coagulopathy, uterine inversion, uterine rupture, vaginal lacerations, and congenital bleeding disorders.

A review of 48,865 women admitted for delivery in the United Kingdom revealed 327 cases meeting the above definition (0.67%), of whom 51 (0.10%) required the transfusion of four or more units of red blood cells.[1] Risk factors for hemorrhage from this report are shown in Table 36–1. Of note, the use of both antidepressants and antiseizure medications increased the risk of hemorrhage. Use of both serotonin reuptake inhibitors[8,9] and valproate[10,11] have been associated with bleeding. Obstetrical hemorrhage was responsible for two thirds of all maternal morbidity seen in their patients. In another series, risk factors for hemorrhage included Asian race, maternal blood disorders, prior postpartum hemorrhage, history of retained placenta, multiple pregnancy, antepartum hemorrhage, genital tract lacerations, macrosomia (>4 kg), induction of labor, chorioamnionitis, stillbirth, compound fetal presentation, epidural anesthesia, prolonged first/second stage of labor, and forceps delivery after a failed vacuum extraction.[12]

Failure of the placenta to deliver spontaneously is an important contributor to postpartum hemorrhage.[13] The phase of delivery during which the placenta is removed is termed the *third stage*. If the third stage of labor is 30 minutes or longer, the risk of postpartum hemorrhage is 6 times higher than in patients whose third stage is less than 30 minutes.[14] After this initial wait time for the placenta to deliver spontaneously, the clinician usually attempts a manual extraction of the placenta to reduce the risk of postpartum hemorrhage, although studies are lacking on the efficacy of this approach. Studies have also found that a prolonged second stage of delivery in nulliparous women increases the risk of postpartum hemorrhage by an odds ratio of 1.16 (95% confidence interval [CI], 1.09–1.24) for each hour of the second stage.[15] Post-term delivery (42 weeks or greater) is associated with an increased risk of postpartum hemorrhage (odds ratio, 1.37; 95% CI, 1.28–1.46).[16] One quarter of women with HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) require transfusion at delivery.[17]

Placenta previa is a complication of pregnancy affecting 0.6% of deliveries in one series of 93,384 deliveries.[18] Hemorrhage due to placenta previa requiring transfusion complicated 25% of deliveries in this series. Patients at greater risk of transfusion were those delivered under general anesthesia and those with a history of previous cesarean section. For those women who require emergency hysterectomy following a cesarean section, the median number of red cells transfused is 6.2 units, with women under regional anesthesia requiring less red cell transfusions (3.3 units vs 6.6 units, $p < 0.005$). A systematic review of the literature found that

Table 36–1 **Risk Factors for Obstetrical Hemorrhage and Their Respective Odds Ratio***

Risk Factor	Odds Ratio	95% Confidence Interval
Manual removal of the placenta	13.12	7.72–22.30
Antidepressant therapy	10.55	2.19–50.71
Iron therapy	5.98	2.28–15.65
Anti-seizure therapy	5.75	1.28–25.72
Emergency cesarean	3.09	2.29–4.17
Underlying social issues	2.91	1.76–4.82
Previous postpartum hemorrhage	2.74	1.69–4.44
Multiple pregnancies	2.29	1.20–4.37
Age over 35 years	1.41	1.03–1.95

*Waterstone M, Bewley S, Wolfe C. Incidence and predictors of severe obstetric morbidity: case-control study. BMJ 2001;322:1089–1094.

the use of neuroaxial blockage with epidural or spinal anesthesia in elective surgery reduced the risk of transfusion.[19]

Uterine rupture is a rare complication of delivery (approximately 0.03% of deliveries), with more than 50% to 90% of cases occurring in women with a history of previous cesarean section.[20,21] Red cell transfusion is required in 25% to 55% of these women, particularly those with complete uterine rupture.[20,21]

Secondary Postpartum Hemorrhage

Secondary postpartum hemorrhage is defined as hemorrhage between 24 hours and 6 weeks after delivery of a degree to warrant obstetrical care.[22] In one series of 19,136 deliveries, 0.8% were complicated by secondary hemorrhage.[23] Contributing factors included early postpartum hemorrhage and manual removal of the placenta.[23] Seventeen percent of patients required transfusion and 64% of patients presented between day 8 and 21. Approximately 2% of women require readmission after initial discharge, with postpartum hemorrhage accounting for a quarter of these readmissions.[24]

Primary Prevention

Spontaneous delivery of the placenta, compared to manual removal, during cesarean section is associated with a reduced risk of hemorrhage and transfusion.[25–27] Sharp incision at the time of cesarean section, as compared to blunt expansion, increases the incidence of postpartum hemorrhage (13% vs. 9%) and need for a transfusion (2% vs 0.4%).[28] Oxytocic therapy used postpartum has been associated with a reduction in the risk of postpartum hemorrhage. The most commonly employed oxytocic drug is synthetic oxytocin. It may be given by intramuscular or intravenous injection either at delivery of the infant shoulder or after delivery of the placenta. Oxytocin is superior to oral misoprostol alone in the prevention of postpartum hemorrhage.[29,30] The combination of oxytocin and misoprostol may reduce the risk of postpartum hemorrhage when compared to either agent alone in the management of the third stage of labor.[31] A bolus injection of oxytocin is more effective than a dilute infusion in the prevention of blood loss.[32] However, bolus injection is rarely associated with coronary vasospasm. Misoprostol alone is no more effective than placebo in the prevention of postpartum hemorrhage.[33–34]

Efforts should be made to correct iron deficiency anemia before the third trimester to reduce likelihood of allogeneic transfusion in the event of a postpartum hemorrhage.[35]

Management

Introduction

Enquiries into maternal deaths suggest that many are avoidable and point to a phenomenon of "too little, too late."[36] Strategies to manage postpartum hemorrhage should be predefined in all obstetrical institutions to ensure rapid and consistent care. Strategies should be in place to prevent delays in pharmacologic strategies, transfusion, embolization, and surgical management. Adherence to a consistent approach to postpartum bleeding is successful in reducing the number of women with massive postpartum hemorrhage.[37]

Pharmacologic Strategies

Oxytocic drugs are the mainstay of treatment and a stepwise approach to them is recommended. The Society of Obstetricians and Gynecologists of Canada published guidelines on the use of these agents in 2005. The reader is directed to the Society's website for the details of this evidence-based guideline.[38]

Several case reports and case series in the literature examine the treatment of refractory postpartum hemorrhage with recombinant activated factor VII.[39–41] The vast majority of published cases show immediate cessation of bleeding. There are no randomized controlled trials in this setting. Randomized controlled trials of recombinant factor VIIa in liver resection,[42] upper gastrointestinal bleeding,[43] and trauma[44] did not show any reduction in transfusion requirements. Randomized clinical trials in both spontaneous intracranial hemorrhage[45] and elective prostate surgery[46] showed promising results. Only in the spontaneous intracranial hemorrhage randomized clinical trial was there a concern regarding excess thromboembolic complications. In the absence of both efficacy and safety data in this population, the current role of this agent remains unknown.

Randomized clinical trial data supports the routine use of antifibrinolytic therapy to reduce hemorrhagic complications and transfusion in cardiac surgery,[47] joint replacement surgery,[48] and liver transplant.[49] The literature in obstetrics is limited to case reports.[50] In the absence of both efficacy and safety data in this population, the current role of antifibrinolytics in the management of postpartum hemorrhage remains unknown.

Interventional Radiology

Uterine artery embolization is a technique used by interventional radiologists to control uterine bleeding from multiple causes. The procedure is usually performed with conscious

sedation or less commonly with general anesthesia. The procedure can be done through either one or both femoral arteries. The uterine artery is reached via the internal iliac artery. Deux and coworkers reported a case series and a review of the literature of uterine artery embolization for the management of postpartum hemorrhage.[51] Of 108 reported attempts at embolization for postpartum hemorrhage, 97% were successful. In 52% of patients, angiography revealed arterial extravasation directing embolization. In the absence of extravasation, bilateral embolization of the uterine arteries was performed. Gelatin foam is preferred because it allows for transient devascularization and thus preservation of fertility. Gelatin foam dissolves in 1 to 3 weeks after the procedure. Complications, seen in 9% of patients, include fever, pain, vaginal abscess, uterine necrosis, and arterial perforation.[52–54] Uncomplicated pregnancy has been reported after embolization of the uterine arteries.[55,56] In one series of 28 women who underwent embolization for hemorrhage, all women who desired to get pregnant were successful and overall had six uncomplicated pregnancies.[57] Case series suggest that embolization before hysterectomy results in fewer complications, less red cell transfusions, shorter stay in intensive care, and preservation of uterine function.[58] Benefits of a primary radiology approach include the avoidance of general anesthesia, avoidance of an open surgical procedure, and the ability to identify and embolize sources of bleeding other than hypogastric arteries. One case report of two patients described arterial balloon occlusion of the internal iliac arteries for 48 hours, instead of embolization, and was successful in stopping uterine bleeding in both.[59]

Surgical Strategies

Multiple surgical strategies have been attempted to arrest ongoing bleeding, including uterine compression sutures,[60] uterine artery ligation (vaginal[61] or abdominal route[62]), and hysterectomy. Cesarean hysterectomy or postpartum hysterectomy (after vaginal delivery) complicates 0.8 per 1000 deliveries, most commonly for management of hemorrhage secondary to uterine atony and placenta accreta.[63] The median blood loss is 3500 mL, requiring a median of 7 units of red cells.[63]

Transfusion Strategies

During an obstetrical hemorrhage, red cells should be administered to maintain the patient free of signs and symptoms of inadequate tissue oxygen delivery. The hemoglobin should be maintained between 60 and 100 g/L during the resuscitation phase. Care should be taken to ensure that all fluids and blood products are warmed prior to infusion and that the appropriate blood tubing is utilized. In the majority of obstetrical hemorrhages there is little advance warning; thus, blood warmers and blood tubing should be available and accessible at all times. Where time allows, the use of other components should be dictated by the results of laboratory testing. During active bleeding the patient's hemoglobin, platelet count, prothrombin time (PT)/International Normalized Ratio (INR), activated partial thromboplastin time (aPTT), and fibrinogen should be monitored frequently to ensure adequate replacement with components. The platelet count should be maintained over 50,000/μL with platelet transfusions and the PT and aPTT should be maintained at less than 1.5 times normal with fresh frozen plasma at a dose of 15 mL/kg. Cryoprecipitate is commonly needed during an obstetrical hemorrhage due to rapid consumption of fibrinogen from disseminated intravascular coagulation. Cryoprecipitate should be administered if the fibrinogen level falls below 1.0 g/L or during a massive hemorrhage where the emergency does not allow one to wait for the results of the fibrinogen assay. The recommended dosage of cyroprecipitate is 1 U per 5 to 10 kg of body weight. Once there is evidence of cessation of bleeding, component use should be restricted to those patients who are deemed at high risk of rebleeding, because rapid restoration of laboratory parameters is seen once hemostasis is achieved.

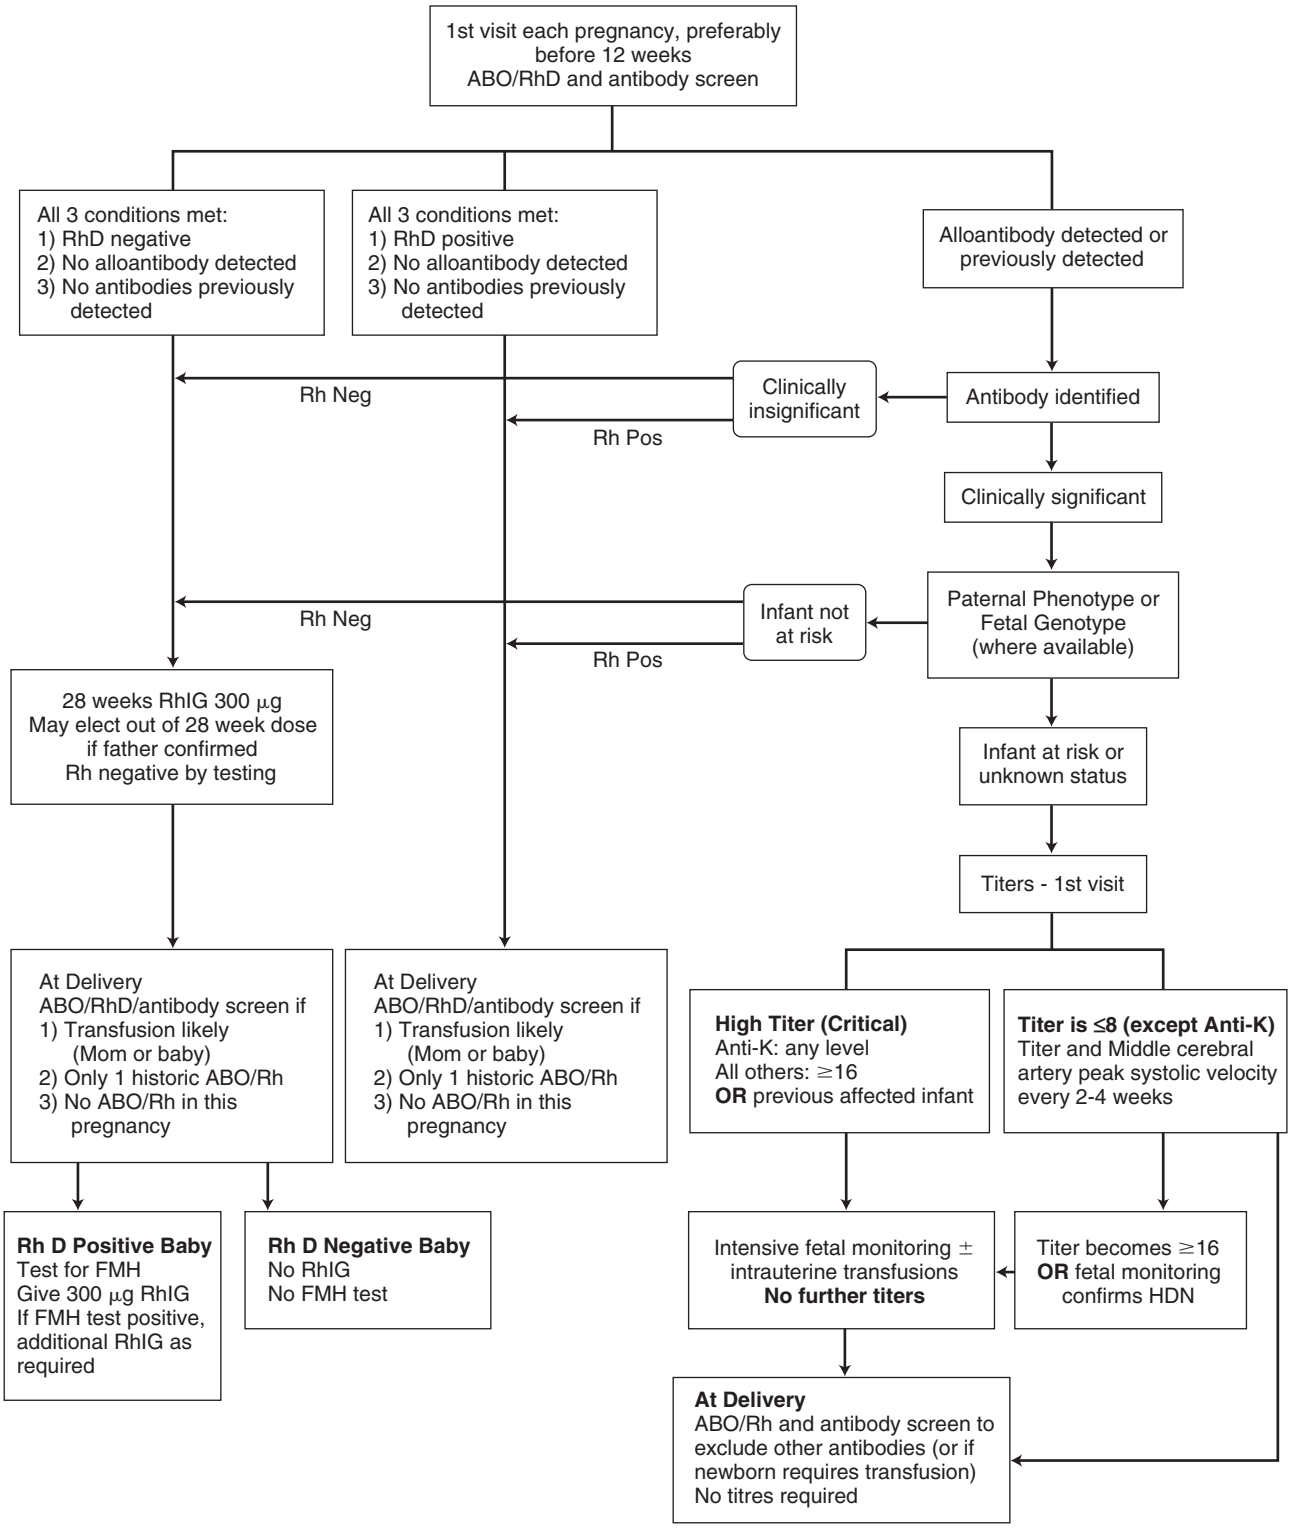
Complications

Complications secondary to postpartum hemorrhage include Sheehan's syndrome,[64] myocardial ischemia,[65] acute renal failure, acute lung injury, and consumptive coagulopathy. Myocardial ischemia is detected in 51% of women with a postpartum hemorrhage of greater than 1000 mL in the setting of hemorrhagic shock, as determined by an elevated cardiac troponin I at 24 hours (median, 10 μg/L; range, 4 to 27 μg/L), electrocardiographic changes, and a reduction in myocardial contractility. Myocardial ischemia is seen particularly in those women with hypotension (<88/50 mmHg) and tachycardia (heart rate > 115 beats/min).[65]

PREVENTION OF RhD ALLOIMMUNIZATION

Prenatal Testing

When developing algorithms for prenatal testing, it is important to ensure that all RhD-negative women are appropriately treated with Rh immune globulin (RhIG) and all clinically important alloantibodies are detected while ensuring a cost-effective testing strategy. A sample algorithm for prenatal testing is shown in Figure 36–1. All pregnant women should be tested for the D antigen and for sensitization to the D antigen, ideally at the first-trimester visit.[66] No further D-antigen testing is required once two concordant D results are obtained during the first pregnancy. The second D-antigen testing is usually performed before the administration of RhIG at 28 weeks or at delivery. The patient's D-antigen status should be re-evaluated with each subsequent pregnancy, including in those patients who are found to be D-positive. Testing for weak expression of the D antigen is not required by the British Committee for Standards in Haematology[67] (United Kingdom), American Association of Blood Banks,[68] or the American College of Obstetricians and Gynecologists.[69] Despite economic pressures, it is unfortunate that 58% of laboratories participating in the College of American Pathologist (CAP) surveys still routinely perform weak D testing on RhD-negative patients.[70] If the decision is made to test for weak expression of the D antigen, women who test positive do not require RhIG. It is not known if women with a partial expression of the D antigen benefit from the administration of RhIG, nor is it known what dose would be required to prevent immunization.[71] Presumably, the maternal red cells would absorb the anti-D, leaving only those immunoglobulin G molecules with specificity for the epitope(s) lacking on the maternal red cells. It is uncertain whether the remaining anti-D is sufficient to prevent alloimmunization in the partial D mother. Notwithstanding, the presence of anti-D has been reported in the plasma of untreated partial D patients, some of whom



1st visit each pregnancy, preferably before 12 weeks
ABO/RhD and antibody screen
All 3 conditions met:
1) RhD negative
2) No alloantibody detected
3) No antibodies previously detected
All 3 conditions met:
1) RhD positive
2) No alloantibody detected
3) No antibodies previously detected
Alloantibody detected or previously detected
Rh Neg
Rh Pos
Clinically insignificant
Antibody identified
Clinically significant
Rh Neg
Rh Pos
Infant not at risk
Paternal Phenotype or Fetal Genotype (where available)
28 weeks RhIG 300 μg
May elect out of 28 week dose if father confirmed Rh negative by testing
Infant at risk or unknown status
Titers - 1st visit
At Delivery
ABO/RhD/antibody screen if
1) Transfusion likely (Mom or baby)
2) Only 1 historic ABO/Rh
3) No ABO/Rh in this pregnancy
At Delivery
ABO/RhD/antibody screen if
1) Transfusion likely (Mom or baby)
2) Only 1 historic ABO/Rh
3) No ABO/Rh in this pregnancy
High Titer (Critical)
Anti-K: any level
All others: ≥16
OR previous affected infant
Titer is ≤8 (except Anti-K)
Titer and Middle cerebral artery peak systolic velocity every 2-4 weeks
Rh D Positive Baby
Test for FMH
Give 300 μg RhIG
If FMH test positive, additional RhIG as required
Rh D Negative Baby
No RhIG
No FMH test
Intensive fetal monitoring ± intrauterine transfusions
No further titers
Titer becomes ≥16
OR fetal monitoring confirms HDN
At Delivery
ABO/Rh and antibody screen to exclude other antibodies (or if newborn requires transfusion)
No titres required

Figure 36–1 Sample algorithm for antenatal and peripartum blood bank testing.

have delivered infants with hemolytic disease of the fetus and newborn (HDFN).[72]

The risk of alloimmunization to the D antigen between the first trimester and 28 weeks' gestation is exceptionally low (0.18%)[73]; therefore, the cost effectiveness of repeat antibody screening before administration of RhIG at 28 weeks has been questioned. Two retrospective series found that routine antibody screening in the third trimester or at delivery was also of low yield (0.06% to 0.24%) and no significant neonatal sequelae resulted from the newly formed antibodies.[74,75] Thus, antibody screening can be safely restricted to those patients at delivery requiring pretransfusion testing or investigation for HDFN. Titration studies after RhIG administration to ensure adequate coverage for prevention of alloimmunization or to differentiate between active and passive anti-D are not useful-nor recommended.[66] There is no data to support the need for an additional dose of RhIG in the last few weeks of pregnancy, even if the antibody screen is found to be negative.

Some clinicians recommend routine pretransfusion testing at delivery on all patients, in case there is a need for an emergency transfusion and the patient has an antibody that was not previously detected. A large retrospective study does not support this opinion.[76] This group estimated that only 1 in 11,050 patients undergoing cesarean sections would have both a new clinically significant antibody and the need for a red cell transfusion. The investigators performed the same analysis for those with vaginal deliveries and found this dual occurrence to be 1 in 61,343 deliveries. Their data supports the practice of withholding pretransfusion testing in patients undergoing vaginal delivery or cesarean section, unless significant risk factors for hemorrhage are present. In the unfortunate event of an unexpected obstetrical hemorrhage, group O, RhD-negative blood should be provided while expediting blood grouping and antibody screening.

Rh Immune Globulin Administration

A combination of an antepartum and a postpartum dose of RhIG reduces the risk of sensitization to 0.1% in clinical studies.[77] All unsensitized RhD-negative women are candidates for RhIG at 28 weeks, at delivery of an RhD-positive fetus, and in the case of spontaneous abortion, ectopic pregnancy, therapeutic abortion, amniocentesis, chorionic villus sampling, external cephalic version, abdominal trauma, antepartum hemorrhage, and other inciting events.[78] If the father of the fetus has been tested and has been shown to be RhD-negative, the woman may elect not to receive RhIG. The paternal sample should be obtained during the current pregnancy, and the result should be placed in the medical records of the pregnant partner. Beyond 20 weeks' gestation, quantification of fetomaternal hemorrhage should be performed to determine if a single dose of RhIG is adequate for prevention of immunization. Such testing must be performed at each inciting event where RhIG administration is required. After 20 weeks, the fetal blood volume exceeds 30 mL[79]; thereafter, a single dose of 300 μg may be insufficient and testing for fetomaternal hemorrhage is recommended.[68,80] Massive fetomaternal hemorrhage may occur without any foreseen cause; therefore, the need for testing should not be dictated by clinical judgment of the risk of fetomaternal hemorrhage.[81] Massive fetomaternal hemorrhage in excess of 30 mL is rare. In one series of 1131 patients tested for fetomaternal hemorrhage by hemoglobin F quantitation, 1.3% were found to have a hemorrhage of greater than 30 mL.[82] If a dose of RhIG is inadvertently not administered within the recommended 72 hours of an inciting event, the dosage should be given as soon as possible and up to 28 days postpartum.[83]

Risks of Rh Immune Globulin

Rh immune globulin is manufactured with multiple viral inactivation strategies to minimize the risk of transmitting blood-borne diseases. The safety strategies include donor selection, donor transmissible disease testing, solvent-detergent viral inactivation, and nanofiltration. Failures in the manufacturing process or donor testing could result in infectious complications. RhIG has been implicated in the transmission of hepatitis C virus in Ireland, where inadequate viral safety measures were in place.[84] In North America, there has been no evidence of viral transmission from this pooled human blood product. Of 624,939 female donors included in a U.S. study to determine the viral safety of RhIG, there were no significant differences in the prevalence of hepatitis C virus and human immunodeficiency virus between Rh-negative and Rh-positive female donors.[85] Adverse drug reactions are uncommon and may include fever and pain at the injection site. Hypersensitivity reactions are rare.[86]

Fetomaternal Hemorrhage Testing

Fetomaternal hemorrhage quantitation is usually performed by acid elution test (Kleihauer-Betke test) or hemoglobin F quantitation by flow cytometry, although other methods are available. The test is performed to determine either the appropriate dosage of RhIG in an RhD-negative mother or to diagnose and quantitate a fetomaternal hemorrhage. The Kleihauer-Betke test has numerous limitations, including low sensitivity, poor reproducibility, and a tendency to overestimate the volume of hemorrhage. An important limitation of the Kleihauer-Betke test is the inability to differentiate between maternal and fetal F cells. This is particularly a problem in the second trimester, when maternal F cells may occasionally reach 5% to 10%. If a Kleihauer-Betke test is performed during this time, this physiologic change may be mistaken for a fetomaternal hemorrhage.

Hemoglobin F quantitation by flow cytometry has been found to be simple, reliable, and more precise than the Kleihauer-Betke test.[82,87] In the 2001 CAP survey, samples representing a 20-mL and a 40-mL bleed were sent as external proficiency testing. Beyond a 30-mL fetomaternal hemorrhage, a single 300-μg dose of RhIG would be insufficient to prevent alloimmunization. For the 20-mL hemorrhage, 88% of laboratories utilizing hemoglobin F quantitation and 50% of the laboratories using the Kleihauer-Betke test correctly reported the result as less than 30 mL. For the 40 mL hemorrhage, 100% of laboratories utilizing hemoglobin F quantitation and 89% of the laboratories using Kleihauer-Betke correctly reported the result as greater than 30 mL. This data suggests that hemoglobin F quantitation may be a superior test method. No clinical management decisions should be based solely on the results of fetomaternal hemorrhage testing given the inaccuracies found in the studies and surveys described above. See Figure 36–2 for sample histograms from control and patient samples tested with the hemoglobin F quantitation method.

MONITORING OF ALLOIMMUNIZATION DURING PREGNANCY

Incidence of Alloimmunization and Hemolytic Disease of the Fetus and Newborn

Overall, approximately 6.8 per 1000 pregnancies are complicated by RhD alloimmunization.[88] In one large series, 1% of pregnancies were shown to be complicated by alloimmunization to antigens implicated in HDFN.[89] The implicated antibody in this series was anti-D in 41%, other Rh antibodies in 30%, and non-Rh antibodies in 29%. In 244 alloimmunized pregnancies, there were 3 intrauterine deaths, 3 fetuses requiring intrauterine transfusion, 10 infants requiring allogeneic transfusion after delivery, and 27 infants requiring phototherapy. Half of Rh-positive infants born to women alloimmunized to the D antigen require no treatment for HDFN.[90] In the presence of

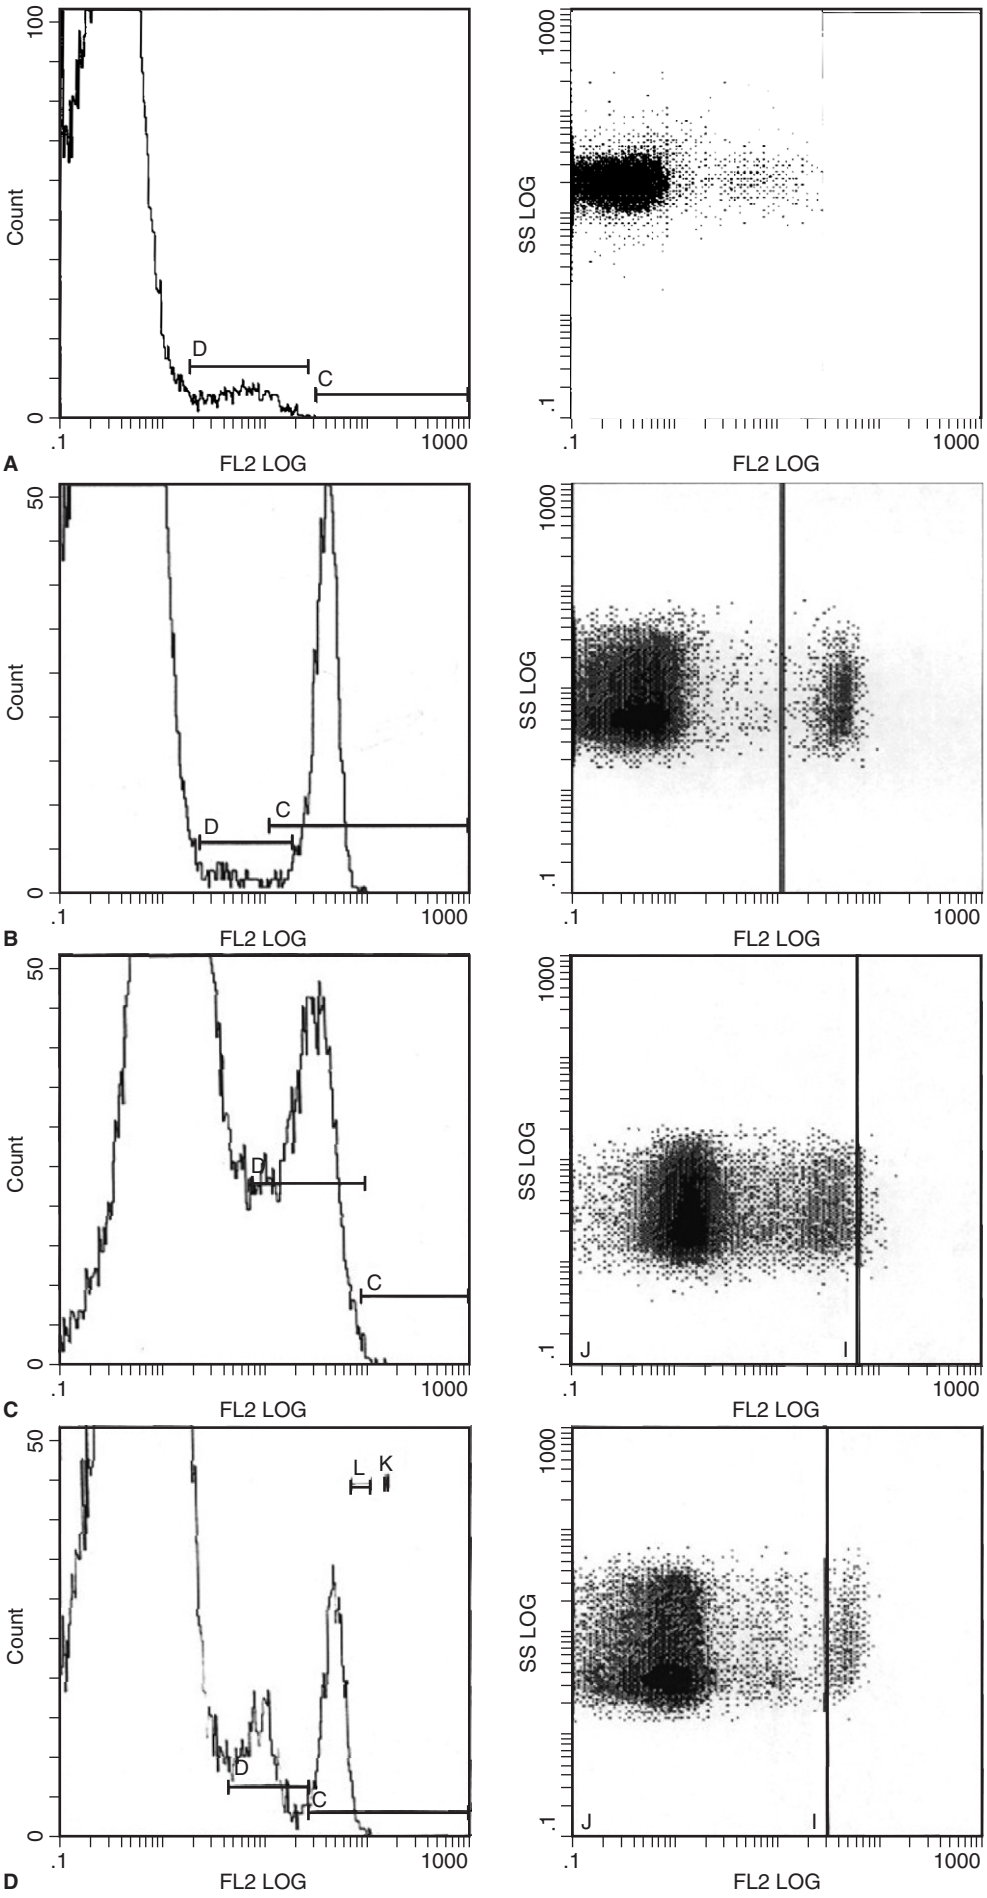


Figure 36–2 Hemoglobin F quantitation performed by flow cytometry with anti–hemogobin F in a nonpregnant control and three patients. For each sample, a quantitative histogram of fluorescence intensity (*left*) and a dot plot representation of side scatter vs. fluorescence (*right*) are shown. Panel A is a female nonpregnant control. Panel B is a patient with a massive fetomaternal hemorrhage (gate C, 7.0%). Panel C is from a woman with a suspected fetomaternal hemorrhage in her second trimester of pregnancy. No fetomaternal hemorrhage was detected, although the patient had a striking increase in maternal F cells (gate D, 15%). Panel D represents a massive fetomaternal hemorrhage (gate C, 3.9%) with a concomitant increase in maternal F cells (gate D, 3.5%). The gating was set with control samples run concurrently with the patient samples.

multiple antibodies, the presence of an anti-D is the single most significant factor predicting the risk of HDFN, with the presence of anti-D plus another antibody further increasing that risk.[91] Table 36–2 details the clinical significance of red cell alloantibodies in HDFN.

Assessing the Severity of Hemolytic Disease of the Fetus and Newborn

Introduction

The role of laboratory testing and fetal imaging is to determine whether intrauterine transfusion or early delivery is warranted in the management of an alloimmunized pregnancy. The risk of complications from such interventions must be weighed against the perceived benefits.

Antibody Titers and Cellular Assays

The role of blood bank testing is to identify the alloantibodies present, to determine their clinical significance, and to perform titrations to assist the clinicians as to when more invasive fetal monitoring is required. An excellent review on the role of titrations has been published and should be reviewed prior to setting testing algorithms.[66] Titers should be performed by the saline tube technique, with previous samples run in parallel. The use of gel technology should be avoided unless validation studies are performed within the laboratory to establish a new critical titer. The use of

Table 36–2 **Potential of Blood Group Alloantibodies to Cause Hemolytic Disease of the Fetus and Newborn (HDFN)***

Blood Group System	Specificity	Severity of HDFN

heterozygous cells and enhancement strategies, such as gel technology, likely explains the wide disparity in titer results seen in external proficiency testing programs. A sample algorithm is shown in Figure 36–1. The *critical titer* varies between laboratories and is approximately 8 to 32 for anti-D.[66,92] The critical titer is thought only to be of value in evaluating the first affected pregnancy.[93] The lack of correlation of titers with fetal outcomes has caused some to question whether titers have any role in the antenatal assessment of alloimmunized pregnancies.[94] A critical titer for non-D antibodies has not yet been defined, and the role of titers for non-D alloimmunization pregnancies remains unclear. Anti-Kell is a clear example of an instance where titers of 4 or less can be associated with HDFN.[95,96] Given the above limitations of titrations, once the critical titer is reached, more invasive testing such as ultrasonography, Doppler assessment of the middle cerebral artery peak systolic velocity, amniocentesis, and cordocentesis is warranted. After the titer has reached a critical level, no further titers should be performed. Titration studies are of no value after delivery. It is recommended that titrations be performed on homozygous cells for the offending antigen and when anti-D is present on R_2R_2 cells, where the expression of the D antigen is more uniform donor to donor.[66] In addition, where available, the current sample should be run in parallel with the previous sample.[97] Titrations should be performed every 2 to 4 weeks after 18 weeks' gestation. If there is a previously affected infant with HDFN, titers should not be performed and more aggressive monitoring should be adopted early in pregnancy.[98]

Cellular assays, such as the monocyte monolayer assay, the chemiluminescence test, and antibody-dependent cell-mediated cytotoxicity assay, which are sensitive to factors affecting antibody function, have been developed to improve the prediction of disease severity.[99] These assays are cumbersome and not broadly available. There are data to suggest that these cellular assays provide clinically useful information to complement serologic testing.[100]

Middle Cerebral Artery Peak Systolic Velocity and Fetal Ultrasonography

Middle cerebral artery peak systolic velocity, measured by Doppler ultrasonography, is an accurate test for detecting fetal anemia.[101,102] This technique is noninvasive and therefore presents no risk of miscarriage or preterm labor, and thus is a preferable method of screening for fetal anemia when compared to invasive alternatives. There is a reciprocal relationship between the fetal hemoglobin concentration and the velocity of cerebral blood flow. Middle cerebral artery peak systolic velocity can also be utilized to predict fetal anemia in non-Rh alloimmunized pregnancies, including anti-K alloimmunized pregnancies.[103] Intrahepatic umbilical venous maximum velocity may also correlate with middle cerebral artery peak systolic velocity and fetal anemia.[103] A threshold value for the peak systolic velocity of 1.50 multiples of the median for gestational age has a 100% sensitivity (95% CI, 86%–100%) for the detection of moderate or severe anemia in fetuses without hydrops.[102] Compared with conventional management, middle cerebral artery peak systolic velocity may have a better predictive accuracy for moderate to severe fetal anemia.[104] Management with middle cerebral artery peak systolic velocity will likely eliminate the need for amniocentesis and reduce the number of periumbilical cord blood samplings performed in red blood cell alloimmunized pregnancies. As ultrasonography evolves and improves, it is extremely likely that titers will prove to be obsolete for predicting which fetuses have significant HDFN.

Invasive Monitoring with Amniocentesis and Periumbilical Cord Blood Sampling

Serial amniocentesis with measurement of the OD450 allowed Liley to divide infants into three risk zones, see Figure 36–3.[105] The timing of repeat amniocentesis or cord blood sampling depends on the level of amniotic fluid bilirubin. Unfortunately, prior to 27 weeks' gestation its reliability

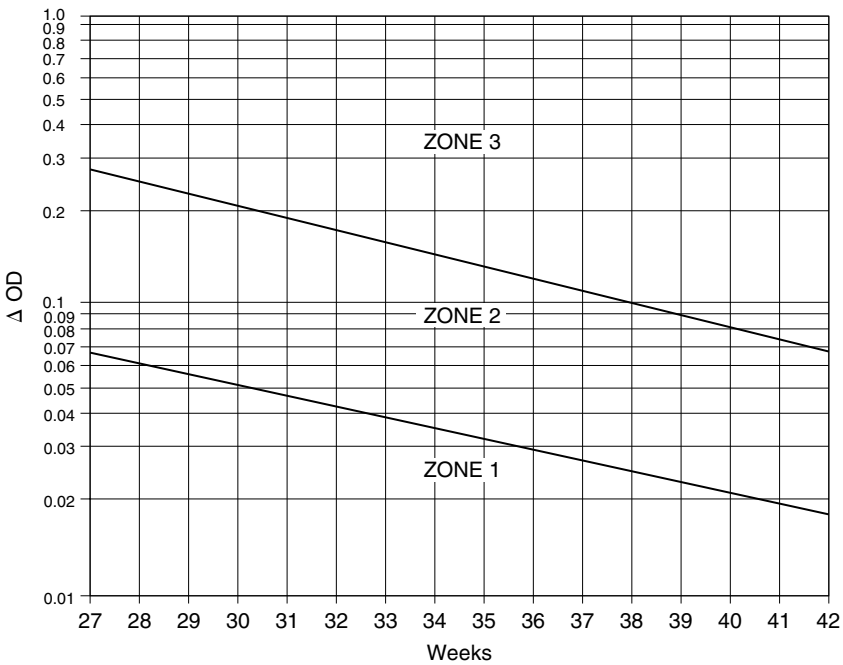

Figure 36–3 Liley graph used to plot degree of alloimmunization. (From American College of Obstetrics and Gynecology. Management of isoimmunization in pregnancy. ACOG Technical Bulletin 227. Washington, D.C., ACOG, 1996, with permission.)

is questionable[106]; the procedure itself may cause fetomaternal hemorrhage, further stimulating alloimmunization[107]; it carries the risk of procedure-related pregnancy loss of 0.6%.[108] Thus, serial middle cerebral artery peak systolic velocity, instead of amniotic fluid OD450 measurement, is used to identify fetuses in whom periumbilical cord blood sampling is required. Once an at-risk infant is identified by either middle cerebral artery peak systolic velocity or amniocentesis, cordocentesis can be used for: measurement of the fetal hemoglobin, reticulocyte count, and bilirubin; determination of blood group; and for performance of the direct antiglobulin test and, where necessary, intrauterine transfusion. Cordocentesis is associated with a risk of fetal loss of approximately 1.0% per procedure.[109,110] Cordocentesis can be complicated by infection, bleeding, fetal bradycardia, intrauterine growth retardation, and premature rupture of the membranes.[109,110]

Fetal Blood Typing

The first step in fetal blood typing is to perform paternal Rh phenotyping for Rh DCE or the offending antigen to determine whether the father is homozygous or heterozygous. If the father is homozygous, all infants will express the offending antigen; and if the father is heterozygous, half of the infants are at risk. Paternal zygosity can be assessed by serologic analysis of the major Rh antigens, and the most probable genotype can be determined by haplotype tables.[111] Alternatively, quantitative polymerase chain reaction analysis can be performed to evaluate genomic DNA for the presence of one or two copies of the RhD gene.[112]

If the fetus is at risk of expressing the antigen, fetal genotyping can be performed on cells obtained from either chorionic villus sampling or amniocentesis. Molecular genotyping is available for most clinically significant antigens; therefore, cordocentesis for fetal red cell phenotyping is not required. Noninvasive methods have been developed to obtain fetal DNA from maternal plasma. This testing is performed simultaneously with maternal and paternal genotyping. Such testing is complicated by the fact that the D-negative status can arise from multiple genetic variations.[113]

MANAGEMENT OF ALLOIMMUNIZATION DURING PREGNANCY

Intrauterine Red Cell Transfusions

Intrauterine transfusions are performed by direct infusion of allogeneic blood into the umbilical cord, the intrahepatic portion of the hepatic vein, or intraperitoneally. Red blood cells are selected to be group O, RhD-negative, Kell-negative, cytomegalovirus-seronegative, leukoreduced, irradiated, hemoglobin S–negative, and less than 72 hours old.[114,115] The unit must also be negative for the offending antigen and crossmatch-compatible with the maternal plasma. Kell-negative red cells are selected to eliminate the risk of immunizing the mother against an additional antigen that has been implicated in severe HDFN. Irradiated red blood cells are warranted to eliminate the risk of transfusion-transmitted graft-versus-host disease (GVHD), especially if maternal red cells are selected for transfusion. In the absence of compatible allogeneic blood, such as alloantibodies to high-frequency antigens, maternal blood is usually selected for transfusion. In rare situations, maternal ABO-mismatched blood is an acceptable source for intrauterine transfusion where antigen-compatible allogeneic blood is unavailable.[116]

The red cell unit should be plasma-reduced to a final hematocrit of 75% to 80%.[93] The red cells should be washed before transfusion if they are older than 7 days or of maternal origin.[117] Intrauterine transfusions become feasible around 20 weeks' gestation when safe cannulation of the umbilical cord can be performed.[118] Intrauterine red cell transfusions may be indicated for reasons other than red cell alloimmunization, including pure red cell aplasia from parvovirus B19 infection, fetomaternal hemorrhage, twin-to-twin transfusion, and hemoglobin Bart's (α-thalassemia with complete absence of all four α-globin genes).

The infant is paralyzed with a short-acting paralytic agent and then the needle is inserted into the umbilical vein under continuous ultrasound guidance. Blood samples are drawn for hematocrit and bilirubin. The amount of blood infused is based on a formula that takes into consideration the fetoplacental volume estimated by fetal weight using ultrasound, the fetal hematocrit, and the unit hematocrit (Fig. 36–4).[114] The final target hematocrit is usually 40%.[93] For severely anemic fetuses, the hematocrit should not be increased by more than fourfold at the first infusion.[119] Samples are also obtained at the completion of the transfusion for final hematocrit and for hemoglobin F quantitation to determine the ratio of transfused red blood cells to fetal red blood cells. Transfusions are repeated every 14 days or less, with the interval based on the rate of decline in the hematocrit from the previous transfusion. Severely affected fetuses may require transfusions as frequently as every 7 days. The final transfusion is performed at or before 35 weeks, with delivery planned at 37 weeks' gestation.

Fetal outcome is superior when intrauterine transfusions are begun before the onset of hydrops (mortality is 22% to 30% for hydropic and 2% to 8% for nonhydropic fetuses).[120,121] The vast majority of infants require only top-up transfusions in the neonatal period for management of their HDFN.[122] Intrauterine transfusions suppress erythropoiesis and can cause hypoproliferative anemia in the neonatal period, especially if the last transfusion occurs close to the time of delivery.[123] It is critical that infants born to alloimmunized mothers receive close follow-up so that late anemia is detected and managed appropriately.

A cohort study of 254 fetuses treated with 740 intrauterine transfusions for red cell alloimmunization between 1988 and 2001 documented the risk of fetal death from procedure-related complications at 1.6%.[124] In this series, the overall procedure-related complication rate was 3.1% (0.1% premature rupture of membranes, 0.3% infection, 2.0% emergency cesarean section, 0.9% fetal death, 0.7% neonatal death). Other known complications of intrauterine transfusion include circulatory overload, splenic rupture, and iron overload.[125–127] Bleeding from the puncture site is thought to occur more

$$\frac{\text{Desired PCV} - \text{Fetal PCV}}{\text{Donor PCV} - \text{Desired PCV}} \times \text{Fetoplacental blood volume}$$

PCV = Packed cell volume

Figure 36–4 Formula for the calculation of the volume of red blood cells required for an intrauterine transfusion. (From Rodeck CH, Dean A. Red cell allo-immunization. In Rodeck CJ, Whittle MJ (eds). Fetal Medicine: Basic Science and Clinical Practice. London, Churchill Livingstone, 1999, pp 785–804.)

frequently when thrombocytopenia and severe hydrops are present, with some physicians recommending routine platelet transfusions for infants with hydrops.[128] Transamniotic cord needling or arterial puncture is thought to increase the incidence of bleeding and both should be avoided. Infants should be closely monitored during and after the procedure. The procedure should be performed in close proximity to the operating room, so that if emergency cesarean section is required it can be performed without delay.

Despite severe fetal hemolytic disease, normal developmental outcome can be expected for children treated with intrauterine transfusions based on a study with long-term follow-up.[129] In this report, 40 children who survived severe HDFN were followed until age 62 months, and no difference was found in the global developmental quotient (101.9 +/− 9.5, compared to the mean for the normal population of 100). There was no correlation between the global developmental quotient and the severity of the HDFN (fetal hematocrit, fetal bilirubin, presence of hydrops fetalis, total number of intrauterine transfusions, duration of neonatal phototherapy, and number of neonatal exchange transfusions).

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) is effective in the postnatal treatment of infants affected with HDFN. In this setting, IVIG reduces the length of hospital stay, the duration of phototherapy, and the need for exchange transfusion (odds ratio, 0.28; CI, 0.17–0.47).[130] Prenatally, the reports of IVIG are limited to encouraging case reports[131] and case series[132,133]; thus, the efficacy of this therapy prenatally is unknown. Encouraging case reports have also been published on the use of plasma exchange and IVIG in the treatment of severe HDFN presenting before intrauterine transfusions are feasible.[134]

Phenobarbital Administration

The rate-limiting enzyme in bilirubin metabolism is bilirubin-UDP-glucuronosyltransferase (UGT1A1). By increasing the expression of UGT1A1, phenobarbital enhances the capacity of the neonatal liver to conjugate and eliminate bilirubin. Phenobarbital binds to a 290–base pair enhancer sequence on the gene for UGT1A1, leading to an increase in the production of this enzyme. A retrospective case-control study found prenatal administration to be effective in decreasing the need for exchange transfusion.[135] Intrauterine transfusions were continued until 35 weeks' gestation. After the last intrauterine transfusion, women were offered phenobarbital 30 mg orally three times a day for 10 days. Delivery was planned after the 10-day treatment. Of 71 women identified with HDFN, 33 were administered phenobarbital. Both the exchange transfusion rate (9% vs 52%, $p < 0.01$) and neonatal mortality rate (0% vs 24%) were reduced by the administration of phenobarbital. After adjusting for gestational age at delivery and neonatal peak total bilirubin, administration of phenobarbital decreased the relative risk of exchange transfusion (risk ratio, 0.23; 95% CI, 0.06–0.76). Halpin and colleagues also found promising results in an earlier report on phenobarbital.[136] These preliminary studies suggest that predelivery phenobarbital is an effective method to prevent exchange transfusion in documented HDFN.

Premature Delivery

Early delivery is performed in all cases of severe HDFN, usually between 35 and 37 weeks' gestation. No data exist to guide the exact timing of delivery in HDFN; however, once fetal lung maturity has been achieved and hemolysis is ongoing, delivery should be expedited.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Incidence

Neonatal alloimmune thrombocytopenia is a serious disorder resulting from platelet–antigen incompatibility between the mother and fetus. It is the most common cause of severe thrombocytopenia in an otherwise healthy infant.[137] Overall, 2.5% of women are HPA-1a negative, with 12% of these mothers having detectable anti-HPA-1a.[138] Thus, 1 of 350 pregnancies is alloimmunized with anti-HPA-1a. The risk of alloimmunization is highest in women who are HLA class II DRB3*0101 (DR52a).[139] The incidence of severe thrombocytopenia secondary to anti-HPA-1a is estimated at 1 in 1000 neonates.[140] The diagnosis is usually made after the discovery of unexpected neonatal thrombocytopenia or when an intracranial hemorrhage is visualized on a routine prenatal ultrasound. Approximately 10% to 20% of affected fetuses have intracranial hemorrhages, one quarter to one half of which occur in utero.[141] The initial platelet count is <20,000/μL in 50% of affected fetuses, including 46% of fetuses sampled before 24 weeks' gestation.[142] Fetuses with HPA-1a incompatibility have more severe thrombocytopenia than fetuses with other platelet–antigen incompatibilities. A history of antenatal intracranial hemorrhage in a sibling predicts a greater severity of thrombocytopenia in a subsequent fetus.[142] One report estimated a 79% risk of intracranial hemorrhage after a diagnosis of intracranial hemorrhage in a previous infant.[143] The literature strongly suggests that neonatal alloimmune thrombocytopenia is currently underdiagnosed.[144] In comparison to HDFN, where first children are rarely affected, 20% to 59% of NAIT cases occur during the first pregnancy.[141]

Etiology

HPA-1a and HPA-5b antibodies are implicated in approximately 80% and 10% of cases of neonatal alloimmune thrombocytopenia, respectively. In one series of 1162 serologically confirmed cases in the United States, the implicated antigens were HPA-1a (79%), HPA-5b (9%), HPA-1b (4%), HPA-3a (2%), and others (6%).[145] Antibody identification is performed using an enzyme-linked immunosorbent assay or monoclonal antibody immobilization of platelet antigens assay. PCR sequence-specific primer assays capable of testing for the 15 HPA allelic variants has been developed and allows for rapid and accurate HPA genotyping.[146] Alternatively, phenotyping can be performed using HPA monoclonal antibodies. Paternal genotyping is performed to determine if the chance of recurrence in a subsequent pregnancy is 100% (HPA-1a/1a) or 50% (HPA-1a/1b).

Management

Maternal Administration of Intravenous Immunoglobulin and Corticosteroids

The role of maternal IVIG, compared to IVIG plus dexamethasone, in the antenatal management of neonatal alloimmune thrombocytopenia was evaluated in a controlled trial of 54 affected pregnancies. No additional benefit was seen with the combination over IVIG alone. Overall, there was a mean platelet increase from the first to the second fetal blood sampling of 36,000/μL and from the first fetal blood sampling to birth of 69,000/μL. A total of 62% to 85% of fetuses responded.[147] In another report, 18 women who had previously delivered infants with severe alloimmune thrombocytopenia were treated with weekly 1 g/kg infusions of IVIG from the diagnosis of fetal thrombocytopenia until birth. Only three treated fetuses had platelet counts of less than 30,000/μL, compared with 16 of 20 untreated siblings.[148] If IVIG treatment fails to give a response, high-dose steroids (60 mg prednisone/day) are often added, although their efficacy is uncertain. Although the above data are limited, antenatal IVIG appears to be a promising therapy. Maternal IVIG is usually commenced when the fetal platelet count by cordocentesis is found to be less than 100,000/μL. Infants are followed for response by both cordocentesis and ultrasonography.

Intrauterine Platelet Transfusions

In the presence of persistent fetal thrombocytopenia, despite maternal IVIG therapy, frequent fetal blood sampling is required to monitor the severity of thrombocytopenia and to provide intrauterine platelet transfusion support for platelet counts of less than 50,0000 to 100,000/μL. Where required for severe thrombocytopenia, the first cordocentesis is usually performed at 22 to 24 weeks' gestation and is repeated at weekly intervals.[149] Antigen-negative, irradiated maternal platelets are recommended. The platelets should be irradiated to eliminate the risk of transfusion-transmitted GVHD. The platelets should be plasma-reduced to minimize the passive transfer of the maternal alloantibodies and resuspended in saline or compatible plasma. Pretransfusion and post-transfusion platelets counts are performed. The median drop in the platelet count after transfusion is approximately 24,000/μL per day; thus, the post-transfusion platelet count can be used to estimate the required interval between procedures.[150] The incidence of fetal loss at the time of each cordocentesis and intrauterine platelet transfusion is estimated at 0.6% to 1.2%.[149,151] Early delivery after achievement of fetal lung maturity is recommended.

Neonatal Platelet Transfusions

Often when a neonate with unexpected thrombocytopenia is suspected of having neonatal alloimmune thrombocytopenia, the management is problematic due to difficulty in obtaining compatible platelets for infusion. Where possible, plasma-depleted, irradiated maternal platelets are recommended because compatibility with maternal antibodies is assured. Maternal platelets can be collected from a unit of whole blood or by platelet apheresis. Where apheresis collection is not immediately available for the collection of maternal platelets, a unit of whole blood can be collected. Once obtained, the unit can be separated into its components in the hospital transfusion service and the autologous red cells can be transfused back to the mother. In addition, the maternal plasma must be tested for transmissible diseases, as required for all allogeneic units. The platelets are almost always required for emergency transfusion before the results of the transmissible disease testing are available. Where maternal platelets are unavailable or unsuitable, matched allogeneic platelets should be obtained. This can be complicated by the delay in obtaining compatible platelets due to the time required for laboratory confirmation of the diagnosis, the identification of compatible donors, the platelet apheresis collection, the donor transmissible disease testing, and the transport of the product to the hospital transfusion service. Several blood suppliers have evaluated the effectiveness of platelet concentrates collected from a panel of donors to maintain an "off-the-shelf" supply of HPA-1a/5b negative platelets, which would be appropriate for 90% of affected neonates.[152] The estimated cost of identifying one eligible HPA-1a/5b negative donor was £8,000, because several thousand donors must be screened to find an eligible donor. It was also suggested that HPA-1a/5b negative platelets be utilized for all neonates, thereby ensuring that most infants with neonatal alloimmune thrombocytopenia would be managed correctly from a platelet transfusion perspective and fewer units would be outdated. The ability to genotype donors on a large scale for HPA-1a/5b may be one means of generating an extensive list of eligible donors to maintain in-date stock of antigen-negative platelets by targeting these donors to enroll as apheresis platelet donors.

Neonatal Intravenous Immunoglobulin

The role of IVIG to treat thrombocytopenia after delivery has been less well-characterized but is often employed.[153] IVIG is usually administered in combination with HPA-matched platelets.

Prevention

Testing all pregnancies to identify women at risk of delivering children with neonatal alloimmune thrombocytopenia secondary to anti-HPA-1a has been studied.[154] The low rate of intracranial hemorrhage in affected pregnancies, the high complication rate from cordocentesis, the lack of certainty on the best course of treatment, and our inability to screen all pregnancies for all platelet alloantibodies have prevented the implementation of widespread population screening for this condition.[155] It is critical that all mothers delivering neonates with unexplained thrombocytopenia should be screened for antibodies implicated in neonatal alloimmune thrombocytopenia to ensure that future pregnancies are appropriately managed.

Chapter 37

Transfusion of Neonates and Pediatric Patients

Cassandra D. Josephson • Ronald G. Strauss*

The principles of transfusion support for older children and adolescents are similar to those for adults, but infants and younger children have many special needs. Therefore, administration of each component to each of these two age groups is discussed separately. Because many issues dealing with transfusion therapy in adults, as discussed in other chapters, apply to older children, the bulk of information in this chapter deals with transfusion in infants and younger children. The following types of components for transfusion will be discussed as they apply to neonates and pediatric patients: red blood cells (RBCs), platelets (PLTs), and neutrophils (granulocytes), fresh frozen plasma (FFP), and cryoprecipitate. General guidelines and recommendations are given for pediatric blood component transfusions. However, it is important that they be adapted to fit local standards of practice. In particular, terms used to describe clinical conditions, such as *severe* and *symptomatic,* must be defined by local physicians.

RED BLOOD CELL TRANSFUSIONS

Older Children and Adolescents

Red blood cells, the most frequently transfused blood component, are given to increase the oxygen-carrying capacity of the blood, the goal being to maintain satisfactory tissue oxygenation. Guidelines for RBC transfusions in older children and adolescents are similar to those for adults (Table 37–1).[1] However, transfusions may be given more stringently to children, because normal hemoglobin (Hb) levels are lower in healthy children than in adults, and most children do not have the concomitant cardiorespiratory and vascular diseases that develop with aging in adults, who then may require more aggressive RBC transfusions.[2] Therefore, children generally have greater abilities to compensate for anemia and may be transfused at lower Hb or hematocrit (Hct) levels.

In the perioperative period or after resuscitation for trauma, it is unnecessary for most children to maintain Hb levels greater than 8.0 g/dL or Hct greater than 24%, a level frequently desired for adults. There should be a compelling reason to administer any postoperative RBC transfusion, because most children (without continued bleeding) can quickly restore their RBC volume if given iron and adequate nutritional therapy.[3] As is true for adults, the most important measures in the treatment of acute hemorrhage occurring with surgery or injury are first to control the hemorrhage and restore blood volume and tissue perfusion with crystalloid and/or colloid solutions. Then, if the estimated blood loss is greater than 25% of the circulating blood volume (i.e., >17 mL/kg body weight) and the patient's condition remains unstable, RBC transfusions may be indicated.

In acutely ill children with severe cardiac or pulmonary disease, particularly in those who require assisted ventilation, it is common practice to maintain the Hb level close to the normal range at a level of 100 to 110 g/L (10 to 11 g/dL) or Hct at 30% to 33%. Although this practice seems logical, its efficacy has not been documented by controlled scientific studies in children, and it has been challenged.[3] The variability of practices in critical care settings was demonstrated by a survey administered to Canadian, French, Belgium, and Swiss pediatric intensivists regarding transfusion practices in a tertiary care pediatric setting. They were queried about patients with bronchiolitis, septic shock, trauma, and about postoperative care of a patient with tetralogy of Fallot. The pretransfusion Hb transfusion "trigger" was 7 to 13 g/dL for the majority of scenarios.[4]

Randomized prospective studies are needed to define optimal pediatric practices because liberal RBC transfusion practices in critically ill adults have been reported to have detrimental effects.[5] A similar harmful effect has been proposed in a retrospective cohort study, including 240 critically ill children (131 transfused and 109 nontransfused; mean age, 5.5 years) with mean initial Hb levels of 7.4 ± 1.4 g/dL, where the number of days of oxygen use, mechanical ventilation, vasoactive agents used, and pediatric intensive care unit and hospital lengths of stay were all significantly increased in association with RBC transfusion.[6] Hospital mortality in the transfused group was 6.9% versus 0.9% ($p = 0.43$) in the nontransfused group. However, mortality could not be adequately evaluated due to the limited number of deaths observed in the study. Overall, the investigators concluded that RBC transfusions are associated with an increase in

*This work was supported in part by National Institutes of Health Program Project Grant P01 HL46925. Transfusions of blood components are mandatory for modern management in many premature infants, children with cancer and hematologic disorders, recipients of hematopoietic progenitor cell transplants and organ allografts, and children undergoing various surgical procedures. Although transfusions can be lifesaving, they are not without risks. Accordingly, they should be given only when true benefits are likely—for example, to correct a deficiency or functional defect of a blood component that has caused or threatens to cause a clinically significant problem. Because of the extended life span of children after transfusions, it is critical to avoid post-transfusion complications that may lead to progressive morbidity and mortality and to considerable expense over the years (e.g., hepatitis).

Table 37–1 **Authors' Guidelines for Transfusing Children and Adolescents***

Red Blood Cells
Hemoglobin < 13.0 g/dL (Hct < 40%) with *severe* cardiopulmonary disease
Hemoglobin < 8.0 g/dL (Hct < 24%) in the perioperative period
Hemoglobin < 8.0 g/dL (Hct < 24%) with *symptomatic* chronic anemia
Hemoglobin < 8.0 g/dL (Hct < 24%) with marrow failure
Acute loss >25% estimated blood volume
Platelets
Blood platelets < 50×10^9/L and *significant* bleeding
Blood platelets < 50×10^9/L and invasive procedure
Blood platelets < 20×10^9/L prophylaxis with bleeding risk factors
Blood platelets < 10×10^9/L prophylaxis without bleeding risk factors
Platelet dysfunction with bleeding or invasive procedure
Neutrophils
Blood neutrophils < 0.5×10^9/L and bacterial infection unresponsive to antibiotics
Blood neutrophils < 0.5×10^9/L and yeast or fungal infection progressing or appearing during treatment with antimicrobials
Neutrophil dysfunction with bacterial, yeast, or fungal infection unresponsive to antimicrobials

*Words in italics must be defined according to local practices.
Hct, hematocrit.

resource utilization in this patient population. Importantly, due to the study's retrospective nature a true cause-and-effect relationship between transfusions and adverse outcomes could not be proven. Obviously, a randomized, controlled clinical trial is essential to help clinicians make more evidence-based decisions regarding when to transfuse RBCs to critically ill children.[6]

With anemias that develop slowly, the decision to transfuse RBCs should not be based solely on the blood Hb concentration, because children with chronic anemias may be asymptomatic despite very low Hb levels. Children with iron deficiency anemia, for example, often are treated successfully with oral iron alone, even at Hb levels lower than 5.0 g/dL. Factors other than Hb concentration that must be considered in the decision to transfuse RBCs include the patient's symptoms, signs, and functional capacities; the presence or absence of cardiorespiratory and central nervous system disease; the cause and anticipated course of the underlying anemia; and use of alternative therapies such as iron or recombinant human erythropoietin (EPO) therapy, the latter of which has been demonstrated to reduce the need for RBC transfusions and to improve the overall condition of children with chronic renal insufficiency. In anemias that are likely to be permanent (e.g., thalassemia, hemoglobinopathies), the effects of anemia on growth and development (which might be ameliorated by RBC transfusions) must be balanced against the potential toxicities of repeated transfusions (e.g., iron overload).

Infants and Younger Children

Pathophysiology of the Anemia of Prematurity

All infants experience a decline in circulating RBC volume during the first weeks of life. This decline results both from physiologic factors and, in sick preterm infants, from phlebotomy blood losses for laboratory monitoring. In healthy full-term infants, the nadir Hb value rarely is lower than 9.0 g/dL at age 10 to 12 weeks. The decline is more rapid (i.e., nadir at age 4 to 6 weeks) and the blood Hb concentration falls to lower levels in infants born prematurely—to approximately 8.0 g/dL in infants with birth weights of 1.0 to 1.5 kg and to approximately 7.0 g/dL in infants with birth weights lower than 1.0 kg.[7–9] Because this postnatal drop in Hb level in full-term infants is well tolerated, it is commonly referred to as the *physiologic anemia of infancy*. However, the pronounced decline in Hb concentration that occurs in many extremely preterm infants is associated with abnormal clinical signs and the need for RBC transfusions. Therefore, the *anemia of prematurity* is not accepted to be a normal, benign event.[10,11]

Many interacting physiologic factors are responsible for the anemia of prematurity. A key reason that the Hb nadir is lower in preterm than in full-term infants is the former group's diminished plasma EPO level in response to anemia.[9,12–15] Although anemia provokes EPO production in premature infants, the plasma levels achieved in anemic infants, at any given Hct, are lower than those observed in comparably anemic older persons.[14] Erythroid progenitor cells in blood[16] and bone marrow[17] of preterm infants are quite responsive to EPO in vitro—a finding suggesting that inadequate production of EPO is the major cause of physiologic anemia, not marrow unresponsiveness.

The mechanisms responsible for the diminished EPO output by preterm neonates are only partially defined. One factor is that the primary site of EPO production in preterm infants is the liver rather than the kidneys.[18,19] Because the liver is less sensitive to anemia and tissue hypoxia, a relatively sluggish EPO response to the falling Hct occurs. The timing of the switch from liver to kidney is set at conception and is not accelerated by preterm birth. Viewed from a teleologic perspective, decreased hepatic production of EPO under in utero conditions of tissue hypoxia may be an advantage for the fetus. If this were not the case, normal levels of fetal hypoxia could trigger high levels of EPO and produce marked erythrocytosis and consequent hyperviscosity in utero. After birth, however, diminished EPO responsiveness to tissue hypoxia is disadvantageous and leads to anemia because of impaired compensation for the falling Hct.

Diminished EPO production cannot entirely explain low plasma EPO levels in preterm infants, however. Extraordinarily high plasma levels of EPO were reported in some fetuses of postconceptional age, comparable to those of neonates treated in intensive care settings,[20,21] and macrophages from human cord blood were found to produce normal quantities of EPO

messenger RNA and protein.[22] These studies documented intact synthetic capability, at least under some circumstances. Therefore, additional mechanisms are likely to contribute to diminished plasma EPO levels. For example, plasma EPO levels undoubtedly are influenced by metabolism (clearance) as well as by production. Data obtained in human infants[23,24] and in neonatal monkeys[25] demonstrate that low plasma EPO levels may result from increased plasma clearance and volume of distribution and from shorter fractional elimination and mean residence times for EPO in neonates compared with adults. Therefore, accelerated catabolism may contribute to the low plasma levels—with the low plasma EPO in infants possibly representing the combined effects of decreased synthesis and increased metabolism.

Phlebotomy blood losses play a key role in the anemia of prematurity. The modern practice of neonatology requires critically ill neonates to be monitored closely with serial laboratory studies such as blood gases, electrolytes, blood counts, and cultures. Small preterm infants are the most critically ill, require the most frequent blood sampling, and suffer the greatest proportional loss of RBCs because their circulating RBC volumes are the smallest. Promising "in-line" devices that withdraw blood, measure multiple analytes, and then reinfuse the sampled blood are being investigated.[26] However, until these devices are proven effective and safe for infants, the replacement of blood losses due to phlebotomy will remain a critical factor responsible for multiple RBC transfusions in critically ill neonates.

Recommendations for RBC Transfusions during Infancy

Guidelines for transfusing RBCs to neonates are controversial, and practices vary.[7,27–29] The lack of a consistent approach stems from incomplete knowledge of the cellular and molecular biology of erythropoiesis during the perinatal period as well as incomplete understanding of the infant's compensation for anemia and the physiologic response to RBC transfusions. Generally, RBC transfusions are given to maintain the level of Hb or Hct believed to be most desirable for each neonate's clinical condition. Broad guidelines for RBC transfusions during early infancy are listed in Table 37–2.[30] These guidelines are very general, and it is important that terms used to describe clinical conditions, such as *severe* and *symptomatic,* be defined to fit local practices.

Most RBC transfusions given to infants are small in volume (10 to 15 mL/kg) and are repeated frequently to replace blood drawn for laboratory studies. There is no proven benefit to routine replacement of phlebotomy blood losses "milliliter for milliliter." Instead, RBCs should be transfused to maintain a Hct level deemed appropriate for the clinical condition of the infant. In neonates with severe respiratory disease, such as those requiring high volumes of oxygen with ventilator support, it is customary to maintain the Hct at greater than 40% (Hb concentration > 13.0 g/dL), particularly if blood is being drawn frequently for testing. This practice is based on the belief that transfused donor RBCs containing adult Hb will provide optimal oxygen delivery throughout the period of diminished pulmonary function that requires mechanical ventilation. Consistent with this rationale for ensuring optimal oxygen delivery in neonates with pulmonary failure, it seems logical—although unproven by controlled studies—to maintain the Hct at greater than 40% in infants with congenital heart disease that is severe enough to cause either cyanosis or congestive heart failure.

Definitive studies are not available to establish the optimal Hb level for infants facing major surgery. However, it seems reasonable to maintain the Hb at greater than 10.0 g/dL (Hct > 30%) because of the limited ability of the infant heart, lungs, and vasculature to compensate for anemia. Additional factors include the inferior off-loading of oxygen by neonatal RBCs that results from the diminished interaction between fetal Hb and 2,3-diphosphoglycerate and from the developmental impairment of neonatal renal, hepatic, and neurologic function. This transfusion guideline is simply a recommendation for perioperative management, not a firm indication, and it should be applied with flexibility to individual infants who are facing surgical procedures of varying complexity.

The clinical indications for RBC transfusions in preterm infants who are not critically ill but nonetheless develop moderate anemia (Hct < 24% or blood Hb concentration < 8.0 g/dL) are extremely variable.[7,29] In general, it was accepted that infants who are clinically stable despite modest anemia do not require RBC transfusions unless they exhibit significant problems that either are ascribed to the presence of anemia or are predicted to be corrected by RBC transfusions. To illustrate, proponents of RBC transfusions to treat disturbances of cardiopulmonary rhythms believe

Table 37–2 **Authors' Guidelines for Transfusing Infants***

Red Blood Cells
Hemoglobin < 13.0 g/dL (Hct< 40%) with *severe* cardiopulmonary disease
Hemoglobin < 10.0 g/dL (Hct< 30%) with *moderate* cardiopulmonary disease
Hemoglobin < 10.0 g/dL (Hct< 30%) with *major* surgery
Hemoglobin < 8.0 g/dL (Hct< 24%) with *symptomatic* anemia
Acute loss > 25% estimated blood volume
Platelets
Blood platelets < 50 to < 100×10^9/L and *significant* bleeding
Blood platelets < 50×10^9/L and invasive procedure
Blood platelets < 20×10^9/L prophylaxis and clinically *stable*
Blood platelets < 50 to < 100×10^9/L prophylaxis and clinically *unstable*
Neutrophils
Blood neutrophils < 3×10^9/L and *fulminant* sepsis during first week of life
Blood neutrophils < 1×10^9/L and *fulminant* sepsis after first week of life

*Words in italics must be defined according to local practices.
Hct, hematocrit.

that a low Hct contributes to tachypnea, dyspnea, apnea, and tachycardia or bradycardia because of decreased oxygen delivery to the respiratory center of the brain. If this theory is true, transfusions of RBCs should decrease the number of apneic spells by improving oxygen delivery to the central nervous system. However, results of clinical studies have been contradictory.[7,29]

A recent study by Bell and colleagues provides evidence to the contrary.[31] In this study, 100 preterm infants, weighing from 500 to 1300 grams, were randomized to either a liberal or restrictive RBC transfusion regimen (i.e., a relatively low or high pretransfusion Hct level, respectively). The investigators found that the mean number of RBC transfusions was higher in the liberal group than the restrictive group; however, because a "single donor/unit program" was used, the number of donor exposures was not statistically significantly different. Furthermore, the most surprising finding was that those infants in the more restrictive group were more likely to have severe grades of intraparenchymal brain hemorrhage or periventricular leukomalacia as well as having increased frequency of apnea. The authors suggest that more restrictive transfusion practices may be detrimental to preterm infants and hypothesize that decreased oxygen delivery to brain tissue may be the pathophysiology of the brain injury and increased frequency of apnea—a speculation supported by another study in which high cerebral fractional oxygen extraction was found in infants with hemorrhagic parenchymal infarction as a manifestation of possible low cerebral blood flow.[31,32] Very importantly, a multicenter study of similar design with only preliminary reports to date[33] found results contradictory to Bell and colleagues. In the randomized study, 451 preterm infants were transfused according to either relatively low or high pretransfusion blood Hb concentrations. In contrast to the findings of Bell and colleagues, no difference in morbidity and mortality were found—favoring acceptance of relatively low pretransfusion blood Hb or Hct levels in clinical practice. Because the experimental design and outcomes were not identical in the two studies, there is no definitive recommendation possible for transfusion practices at this time. However, the potential for harm due to "undertransfusion," if very low pretransfusion Hb or Hct levels are accepted, must be considered when transfusion decisions are made.

Generally in practice, the decision whether to transfuse RBCs is based on the desire to maintain the Hct at a level judged to be most beneficial for the infant's clinical condition. Investigators who believe that this "clinical" approach is too imprecise have suggested the use of "physiologic" criteria for transfusions, such as RBC mass,[34] available oxygen,[35] mixed venous oxygen saturation, or measures of oxygen delivery and utilization,[36] to develop guidelines for transfusion decisions. In one study of 10 infants with severe (oxygen-dependent) bronchopulmonary dysplasia, improvement in physiologic end points (increased systemic oxygen transport and decreased oxygen use) was shown to be a consequence of small-volume RBC transfusions.[36] However, these promising but technically demanding methods are, at present, difficult to apply in the day-to-day practice of neonatology, and studies conducted directly in infants are needed. Application of data obtained from studies of animals and adult humans that correlate tissue oxygenation with the clinical effects of anemia and the need for RBC transfusions is confounded by the differences between infants and adults in Hb oxygen affinity, ability to increase cardiac output, and regional patterns of blood flow.

Another physiologic factor to be considered in the transfusion decision is the use of circulating RBC volume rather than blood Hct or Hb level.[11,34,37] Although circulating RBC volume is a potentially useful index of the blood's oxygen-carrying capacity, it cannot be predicted accurately by measurement of the Hct in infants.[38] Low circulating RBC volume identifies, better than Hb or Hct, those infants who will respond to transfusion with a decrease in cardiac output.[39] At present, circulating RBC volume measurements are not widely available. However, promising techniques using nonradioactive biotin to tag RBCs have been adapted for infant studies. Strauss and coworkers were able to demonstrate with this technique that the post-transfusion recovery and in vivo survival of donor RBCs, stored for up to 42 days, confirmed earlier studies that defined the efficacy and safety of stored allogeneic RBCs for small-volume transfusions to neonates. Specifically, no significant differences were observed between allogeneic RBCs stored on days 1 to 21 compared to days 22 to 42.[39–41]

Selecting an RBC Product to Transfuse an Infant

The RBC products usually chosen for small-volume transfusions given to infants are RBCs suspended either in citrate-phosphate-dextrose-adenine solution (CPDA) or in extended storage media (AS-1, AS-3, AS-5) at a Hct ranging from 55% to 70%. Some centers prefer to centrifuge RBC aliquots before transfusion, to prepare packed RBCs at a Hct of 80% to 90%. Most RBC transfusions are infused slowly over 2 to 4 hours at a dose of about 15 mL/kg body weight. Because of the small quantity of RBC preservative fluid infused and the slow rate of transfusion, the type of anticoagulant/preservative medium selected is believed not to pose risks for the majority of premature infants given small-volume transfusions.[42] Accordingly, the traditional use of relatively fresh RBCs (<7 days of storage) has been challenged, and it has been shown by many investigators[43–45] that donor exposure of multiply transfused infants can be diminished safely by the exclusive use of a dedicated unit of stored RBCs (i.e., 21 to 42 days after collection) for each infant.

Neonatologists who object to stored RBCs and continue to insist on transfusing infants with fresh RBCs generally raise three objections: the rise in plasma potassium (K^+) and the drop in RBC 2,3-diphosphoglycerate that occur during extended storage and the possible dangers of additives present in extended-storage media. After 42 days of storage, plasma K^+ levels in RBC units approximate 50 mEq/L (0.05 mEq/mL), a value that, at first glance, seems alarmingly high. By simple calculations, however, the dose of bioavailable K^+ transfused (i.e., ionic K^+ in the extracellular fluid) is shown to be very small. An infant weighing 1 kg who is given a 15 mL/kg transfusion of packed RBCs (Hct, 80%) will receive 3 mL of extracellular fluid, containing only 0.15 mEq of K^+, which will be infused slowly. Even if RBCs are not packed but are removed from the blood bag and directly infused at a Hct of 60%, the K^+ dose will be only 0.3 mEq. These doses are quite small compared with the usual daily K^+ requirement of 2 to 3 mEq/kg. However, this rationale does not apply to large-volume transfusions (>25 mL/kg), in which larger doses of K^+ may be harmful, especially if the infusion is rapid. Cardiac surgeons and other pediatric surgeons who may transfuse large RBC volumes expectedly or unexpectedly need to be especially cognizant of this point.

As for the second objection, 2,3-diphosphoglycerate is totally depleted from RBCs by 21 days of storage, and

Table 37–3 **Formulation of Anticoagulant-Preservative Solutions Present in Blood Collection Sets**

Constituent	CPDA	AS-1	AS-3	AS-5
Volume (mL)	63*	100†	100†	100†
Sodium chloride (mg)	None	900	410	877
Dextrose (mg)	2000	2200	1100	900
Adenine (mg)	17.3	27	30	30
Mannitol (mg)	None	750	None	525
Trisodium citrate (mg)	1660	None	588	None
Citric acid (mg)	206	None	42	None
Sodium phosphate (monobasic) (mg)	140	None	276	None

*Approximately 450 mL of donor blood is drawn into 63 mL of CPDA. A unit of red blood cells (hematocrit, approximately 70%) is prepared by centrifugation and removal of most plasma.

†When AS-1 or AS-5 is used, 450 mL of donor blood is first drawn into 63 mL of CPD, which is identical to CPDA except that it contains 1610 mg of dextrose per 63 mL and has no adenine. When AS-3 is used, donor blood is drawn into CP2D, which is identical to CPD except that it contains double the amount of dextrose. After centrifugation and removal of almost all plasma, red blood cells are resuspended in 100 mL of the additive solution (AS-1, AS-3, or AS-5) at a hematocrit of approximately 55% to 60%.

AS-1, AS-3, and AS-5, extended storage media; CPDA, citrate-phosphate-dextrose-adenine solution.

this is reflected by a decrease in the oxygen half-saturation pressure (P_{50}) from about 27 mmHg in fresh blood to 18-mmHg at the time of outdate. The last value of older transfused RBCs corresponds to the "physiologic" P_{50} obtained from the RBCs of many normal preterm infants at birth, reflecting the relatively high affinity for oxygen normally exhibited by infant RBCs. Therefore, the P_{50} of older transfused RBCs is no worse than that of RBCs produced endogenously by the infant's own bone marrow. Moreover, these older adult RBCs provide a benefit to the infant because the 2,3-diphosphoglycerate and the P_{50} of transfused RBCs (but not of endogenous infant RBCs) increase rapidly after transfusion.

Regarding the third objection, the quantity of additives present in RBCs stored in extended-storage media is believed not to be dangerous to neonates given small-volume transfusions (≤15 mL/kg).[42] A comparison of CPDA with three types of extended-storage media is presented in Table 37–3. Regardless of the type of suspending solution, the quantity of additives is quite small in the clinical setting, in which infants are given small-volume transfusions of RBCs transfused over 2 to 4 hours, and it is far lower than doses believed to be toxic (Table 37–4). Importantly, the efficacy and safety of these theoretical calculations have been confirmed by clinical experience. In addition, many investigators have reported the successful transfusion of stored, rather than fresh, RBCs for small-volume transfusions in infants.[43–46] The small-volume nature of these transfusions cannot be overemphasized. Therefore, these same rules do not apply to massive transfusion situations, which many pediatric surgeons and neonatologists may encounter knowingly or unknowingly and for which they need to be prepared accordingly. This information is especially important for surgeons and neonatologists who are recommending that the parents, relatives, or friends of their patients perform directed RBC donation. Communication between the physicians and blood bank is encouraged for many reasons: to confirm the child's blood type so type-compatible RBCs can be donated; to help with the collection center's choice of anticoagulant-preservative solution into which the units will be drawn (i.e., CPDA and/or AS units), which might differ if a massive transfusion situation seems likely; and to coordinate timing of the surgery so that tested units are in hospital inventory prior to the surgical date and time.

Recombinant Erythropoietin in the Anemia of Prematurity

Recognition of the low plasma EPO levels in preterm infants provides a rational basis for the use of recombinant human EPO as therapy for the anemia of prematurity. More than 20 controlled trials have tested several doses and treatment schedules in preterm infants, and results are mixed, making consensus impossible on the optimal role of recombinant human EPO treatment in the anemia of prematurity.[7,47,48]

Table 37–4 **Constituents Infused (mg/kg) in 10 mL/kg Red Blood Cells (Hematocrit, 60%)**

Additive	CPDA	AS-1	AS-3	Toxic Dose*
NaCl	0	28	5	137 mg/kg/day
Dextrose	13	86	15	240 mg/kg/hr
Adenine	0.2	0.4	0.4	15 mg/kg/dose
Citrate	12	6.5	8.4	180 mg/kg/hr
Phosphate	9	1.3	3.7	>60 mg/kg/day
Mannitol	0	22	0	360 mg/kg/day

*Actual toxic dose is difficult to predict accurately because the infusion rate usually is slow, permitting metabolism and distribution from blood into extravascular sites, and dextrose, adenine, and phosphate enter red blood cells and are somewhat sequestered. Potential toxic doses are based on Luban, Strauss, and Hume (1990).[32]

AS-1 and AS-3, extended storage media; CPDA, citrate-phosphate-dextrose-adenine solution.

Data from Luban NLC, Strauss RG, Hume HA. Commentary on the safety of red blood cells preserved in extended storage media for neonatal transfusions. Transfusion 1990;30:229.

Unquestionably, proper doses of recombinant human EPO and iron effectively stimulate erythropoiesis in preterm infants, as evidenced by increased marrow erythroid activity and blood reticulocyte counts. However, the efficacy of recombinant human EPO in substantially diminishing the number of RBC transfusions—the major goal for which it is prescribed—has not been convincingly demonstrated for all groups of preterm infants.[48] In many trials, the subjects were relatively large preterm infants and those in stable clinical condition; such infants currently receive few RBC transfusions when given only standard supportive care (i.e., not given recombinant human EPO).[27,49] Currently, even without use of recombinant human EPO, fewer than 50% of infants with birth weights greater than 1.0 kg receive RBC transfusions. Almost all infants weighing less than 1.0 kg at birth are given RBCs, and most transfusions are given during the first 3 to 4 weeks of life.[49]

To illustrate the difficulty of avoiding RBC transfusions, a multicenter, randomized North American trial, in which infants received either recombinant human EPO or placebo during a 6-week study period, reported a statistically significant difference but only modest success.[50] Although significantly fewer RBC transfusions were given to infants treated with recombinant human EPO during the study phase (1.1 transfusion vs 1.6 for placebo), all infants required multiple transfusions during the 3-week prestudy phase. Therefore, recombinant human EPO exerted only a modest effect on total RBC transfusions given throughout the entire study (4.4 for recombinant human EPO vs 5.3 for placebo) and did not resolve the problem of severe neonatal anemia.[50]

Physicians wishing to prescribe recombinant human EPO are faced with a dilemma. The relatively large or stable preterm infants who respond best to recombinant human EPO plus iron are given relatively few RBC transfusions and, accordingly, have little need for recombinant human EPO to avoid transfusions. Extremely preterm infants, who are sick and have the greatest need for RBC transfusions shortly after birth, have not consistently responded to recombinant human EPO plus iron, again questioning the efficacy of recombinant human EPO therapy.[47] However, extremely preterm infants are being evaluated in therapeutic trials of recombinant human EPO and iron, both given intravenously shortly after birth.[51,52] Although preliminary review of these promising studies suggests success in avoiding transfusions early in life, the data are limited and are insufficient to clearly establish efficacy or to detect potential toxicity. Therefore, firm guidelines for the use of recombinant human EPO in the treatment of the anemia of prematurity cannot be offered at this time.

PLATELET TRANSFUSIONS

Older Children and Adolescents

Guidelines for platelet support of children and adolescents with quantitative and qualitative platelet disorders are similar to those for adults (see Table 37–1), in whom the risk of life-threatening bleeding that occurs after injury or spontaneously can be related to the severity of thrombocytopenia (when low blood platelet counts are caused by diminished marrow production). Thrombocytopenia caused by accelerated turnover (e.g., immune thrombocytopenia) usually is not treated with platelet transfusions. Platelet transfusions should be given to patients with platelet counts lower than 50×10^9/L due to marrow failure if they are bleeding or are scheduled for an invasive procedure. Studies of patients with thrombocytopenia caused by poor marrow production indicate that spontaneous bleeding increases markedly when platelet levels fall to less than 20×10^9/L, particularly in patients who are ill with infection, anemia, or dysfunction of the liver, kidneys, or lungs. For this reason, many pediatricians recommend prophylactic platelet transfusions to maintain the platelet count at greater than 20×10^9/L in children with thrombocytopenia due to bone marrow failure. This threshold has been challenged, and some favor a platelet transfusion trigger of 5 to 10×10^9/L for patients with uncomplicated conditions. Many pediatric hematology/oncology and stem cell transplantation physicians have lowered their prophylactic platelet transfusion trigger to 10×10^9/L, extrapolating from the adult acute myeloid leukemia studies by Rebulla and colleagues in 1997 and Wandt and coworkers in 1998.[53,54] These prospective clinical trials, among others, demonstrated that nonbleeding stable thrombocytopenic patients without coexisting symptoms can be managed safely with a more restrictive platelet transfusion trigger, 10×10^9/L, and fewer platelet transfusions were given. However, those with fever, active bleeding, and/or a coagulation disorder had a higher trigger of at least 20×10^9/L.

Qualitative platelet disorders may be inherited or acquired (e.g., in advanced hepatic or renal insufficiency, after cardiopulmonary bypass procedures). In such patients, platelet transfusions are justified only if significant bleeding occurs. Because individuals with platelet dysfunction may have intermittent bleeding episodes throughout their life necessitating repeated transfusions, which may lead to alloimmunization and refractoriness, prophylactic platelet transfusions are rarely justified unless an invasive procedure is planned. In such cases, a bleeding time greater than twice the upper limit of laboratory normal may be taken as diagnostic evidence that platelet dysfunction exists, but this test is poorly predictive of hemorrhagic risk or the need to transfuse platelets. The bleeding time has been supplanted by other platelet function assays and is rarely performed anymore, especially in children. In these patients, alternative therapies, particularly subcutaneous or intranasal desmopressin acetate, should be considered to avoid platelet transfusions.

Infants and Younger Children

Pathophysiology of Neonatal Thrombocytopenia

Blood platelet counts of 150×10^9/L or greater are present in normal fetuses (=17 weeks of gestation) and neonates. Lower platelet counts indicate potential problems, and preterm infants exhibit thrombocytopenia commonly.[55,56] In one neonatal intensive care unit, 22% of infants had blood platelet counts lower than 150×10^9/L during hospitalization.[55] Although multiple pathogenic mechanisms probably are involved in these sick neonates, a predominant one is accelerated platelet destruction, as shown by shortened platelet survival time, increased platelet-associated immunoglobulin G, increased platelet volume, a normal number of megakaryocytes, and an inadequate increment in blood platelet values after platelet transfusion.[55,57] Another major mechanism contributing to neonatal thrombocytopenia is diminished platelet production, as evidenced by decreased

numbers of clonogenic megakaryocyte progenitors[58,59] and relatively low levels of thrombopoietin[59,60] in response to thrombocytopenia, when compared with children and adults. Similar to the situation with EPO and the anemia of prematurity, thrombopoietin is produced by thrombocytopenic preterm infants, but at relatively low levels. Controlled clinical trials are needed to determine the possible role and potential toxicity of recombinant thrombopoietin therapy in infants.

Blood platelet counts lower than 100×10^9/L pose significant clinical risks for premature neonates. In one study, infants with birth weights lower than 1.5 kg and blood platelet counts lower than 100×10^9/L were compared with nonthrombocytopenic control infants of similar size.[56] The bleeding time was prolonged when platelet counts were lower than 100×10^9/L, and in many infants platelet dysfunction was suggested by bleeding times that were disproportionately long for the degree of thrombocytopenia present. Hemorrhage was more frequent in the thrombocytopenic infants, with the incidence of intracranial hemorrhage being 78% in those weighing less than 1.5 kg at birth, compared with 48% for nonthrombocytopenic infants of similar size. Moreover, the extent of hemorrhage and neurologic morbidity was greater in the group of thrombocytopenic infants.[56]

Recommendations for Platelet Transfusions during Infancy

The use of prophylactic platelet transfusions in an attempt to prevent bleeding in preterm neonates has been studied systematically.[61] However, no randomized clinical trials have been reported examining therapeutic platelet transfusions in bleeding thrombocytopenic neonates. Therefore, basic questions regarding the relative risks of different degrees of thrombocytopenia in various clinical settings during infancy remain largely unanswered. However, it seems logical to transfuse platelets to thrombocytopenic infants, and guidelines acceptable to many neonatologists are listed in Table 37–2. Two firm indications for neonatal platelet transfusions are to treat hemorrhage that has already occurred and to prevent hemorrhage from complicating an invasive procedure. Little disagreement exists regarding the use of a blood platelet count lower than 50×10^9/L as a "transfusion trigger" in these instances. However, platelet transfusions are given to infants by some physicians to treat bleeding that occurs at higher platelet counts (between 50 and 100×10^9/L) or to diminish the threat of intracranial hemorrhage in high-risk preterm infants whenever the platelet count is lower than 100×10^9/L.[56]

Prophylactic platelet transfusions can be given under two circumstances: to prevent bleeding when severe thrombocytopenia is present and poses a risk of spontaneous hemorrhage and to maintain the presence of a normal platelet count to prevent the infant from slipping into high-risk situations. Regarding the first circumstance, most agree that it is reasonable to give platelets to any neonate whose blood platelet count is lower than 20×10^9/L. There is broad acceptance that spontaneous hemorrhage is a risk with platelet counts below this level. Also, severe thrombocytopenia occurs most commonly in sick infants who, because of their illnesses, receive medications that may further compromise platelet function. Because all of these factors are pronounced in extremely preterm infants, some neonatologists favor prophylactic platelet transfusion whenever the platelet count falls to less than 50×10^9/L, or even 100×10^9/L, in critically ill infants.[56]

Regarding the second circumstance, the need to maintain a completely normal platelet count ($\geq 150 \times 10^9$/L) or even higher in preterm infants without bleeding is unproven. Intracranial hemorrhage occurs commonly in sick preterm infants, and, although the etiologic role of thrombocytopenia and the therapeutic benefit of platelet transfusions have not been conclusively established in this disorder, it seems logical to presume that thrombocytopenia is a risk factor.[62] However, a randomized trial designed to address this issue—in which transfusion of platelets whenever the platelet count fell to less than 150×10^9/L so as to maintain the average platelet count at greater than 200×10^9/L was compared with transfusion of platelets only when the platelet count fell to less than 50×10^9/L—did not detect a difference in the incidence of intacranial hemorrhage (28% vs 26%, respectively).[61] Therefore, there is no documented benefit to transfusing "prophylactic platelets" to maintain a completely normal platelet count, compared with transfusing "therapeutic platelets" in response to thrombocytopenia when it actually occurs.

Currently, there are no alternatives to platelet transfusions to treat thrombocytopenia in neonates. Recombinant thrombopoietin (i.e., c-*mpl* ligand or megakaryocyte growth and differentiation factor) and interleukin-11 are promising agents. However, neither is recommended for use during infancy, and both have potential toxicities that might preclude their use in sick preterm infants. Clearly, they must not be prescribed at present, except in experimental settings.

Selecting a Platelet Product to Transfuse an Infant or Younger Child

The ideal goal of most platelet transfusions is to raise the platelet count to greater than 50×10^9/L or, for sick preterm infants, to greater than 100×10^9/L. This goal can be achieved by the infusion of 5 to 10 mL/kg of standard (i.e., unmodified) platelet concentrates, collected by centrifugation of fresh units of whole blood or from a plateletpheresis unit collected by automated plateletpheresis. The platelet dose should be transfused as rapidly as the overall condition permits, certainly within 2 hours. Routinely reducing the volume of platelet concentrates for infants by additional centrifugation steps is both unnecessary and unwise. Transfusion of 10 mL/kg platelet concentrate provides approximately 10×10^9/L platelets. Assuming that the estimated blood volume of an infant is 70 mL/kg body weight, the platelet dose of 10 mL/kg will increase the platelet count by 143×10^9/L. This calculated increment is consistent with the observed increment after this dose reported in clinical studies.[61] In general, 10 mL/kg is not an excessive transfusion volume, provided that the intake of other intravenous fluids, medications, and nutrients is monitored and adjusted. It is desirable that the infant and the platelet donor be of the same ABO blood group, and it is important to minimize repeated transfusions of group O platelets to group A or B recipients, because large quantities of passive anti-A or anti-B can lead to hemolysis, resulting in severe morbidity and mortality in children.[63–66]

Although proven methods exist to reduce the volume of platelet concentrates when truly warranted (i.e., when many transfusions are anticipated in which multiple doses of passive anti-A or anti-B might lead to hemolysis or when there is failure to respond to 10 mL/kg of unmodified platelet concentrate), additional processing (i.e., plasma volume reduction) should be performed with great care because of

probable platelet loss, clumping, and dysfunction caused by the additional handling.

NEUTROPHIL TRANSFUSIONS

Older Children and Adolescents

Several methodologic advances—in particular, the use of recombinant granulocyte colony-stimulating factor (G-CSF) to stimulate donors—have made it possible to collect extraordinarily large numbers of normal neutrophils (polymorphonuclear neutrophils, PMNs) for transfusion into neutropenic patients who have life-threatening infections. Because larger doses of PMNs can be transfused, renewed interest has arisen in the use of PMN (granulocyte) transfusions to treat adult oncology patients and hematopoietic progenitor cell transplant recipients, in whom neutropenia complicated by severe infections persists as a significant problem despite combination antibiotic therapy, recombinant cytokines, myeloid growth factors, and use of mobilized peripheral blood progenitor cells to minimize neutropenic infections. If children are suffering significant morbidity and mortality from neutropenic infections despite modern supportive care, it is logical to explore the efficacy, potential toxicity, and cost effectiveness of tranulocyte transfusion therapy through properly designed, randomized clinical trials performed in pediatric subjects.[67]

Serious and repeated infections with bacteria, yeast, and fungi are a consequence of severe neutropenia and PMN dysfunction in some settings. In the multicenter Trial to Reduce Alloimmunization to Platelets (TRAP) study, 7% of adult patients with acute nonlymphocytic leukemia died from infection during first-remission induction therapy, despite the use of modern antibiotic therapy.[68] In another study of patients given intensive chemotherapy, some of whom also received transfusions of autologous hematopoietic stem cells, 7.6% of patients experienced systemic fungal infection.[69] Unless severe neutropenia is reversed fairly quickly in adult patients, the mortality of systemic fungal infections approaches 100%. Therefore, modern "high-dose" granulocyte transfusion therapy is considered by some experts to be very promising for adult oncology and transplantation patients.[70,71] However, contrary data suggest that, with appropriate anti-infective therapy, serious infections are rare in patients who are transplanted with adequate numbers of peripheral blood progenitor cells.[72]

Because of these controversial views, pediatricians must survey the outcome of life-threatening infections with bacteria, yeast, and fungi in children who are undergoing intense chemotherapy or hematopoietic progenitor cell transplantation in their own institutions to determine whether there is a need for therapeutic granulocyte transfusion. If infections in neutropenic children respond promptly to antibiotics plus standard supportive care and survival approaches 100%, granulocyte transfusion is unnecessary. Moreover, it should not be used if there is no apparent need, because the lack of demonstrable benefit would not outweigh the potential risks. However, if significant numbers of infected high-risk patients fail to respond to antibiotics alone, or if the intensity of therapy is compromised because it is limited by fear of neutropenia, the addition of granulocyte transfusion should be considered, along with other modifications of therapy intended to reduce infections, such as selection of different antibiotics, closer monitoring of antibiotic blood levels, and use of intravenous immunoglobulin (IVIG), G-CSF, other recombinant cytokines, and immune-modulating agents.

The role of granulocyte transfusion added to antibiotics for patients with severe neutropenia ($<0.5 \times 10^9$/L) caused by bone marrow failure is similar in adults and children (see Table 37–1). Infected neutropenic patients usually respond to antibiotics alone, provided bone marrow function recovers early in infection. Because children with newly diagnosed leukemia respond rapidly to induction chemotherapy, only rarely are they candidates for granulocyte transfusion. In contrast, infected children with sustained bone marrow failure (e.g., malignant neoplasms resistant to treatment, aplastic anemia, bone marrow transplantation) may benefit from the addition of granulocyte transfusion to antibiotic therapy. The use of granulocyte transfusion for bacterial sepsis that is unresponsive to antibiotics in patients with severe neutropenia ($<0.5 \times 10^9$/L) is supported by most controlled studies.[67,70]

Children with qualitative neutrophil defects (neutrophil dysfunction) usually have adequate numbers of blood neutrophils but are susceptible to serious infections because their cells kill pathogenic microorganisms inefficiently. Neutrophil dysfunction syndromes are rare, and no definitive studies have established the efficacy of granulocyte transfusion in these patients. However, several patients with progressive life-threatening infections have improved strikingly with the addition of granulocyte transfusion to antimicrobial therapy.[73] These disorders are chronic, and because of the risk of inducing alloimmunization, GTX is recommended only if the infections are clearly unresponsive to antimicrobial drugs.

Infants and Younger Children

Pathophysiology of Neonatal Neutropenia and Neutrophil Dysfunction

Neonates are unusually susceptible to severe bacterial infections, and several defects of neonatal body defenses have been reported as possible contributing factors. PMNs isolated from the blood of neonates exhibit both quantitative and qualitative abnormalities that may be related to the increased incidence, morbidity, and mortality of bacterial infections. Abnormalities of neonatal PMNs include absolute and relative neutropenia, diminished chemotaxis, abnormal adhesion and aggregation, defective cellular orientation and receptor capping, decreased deformability, inability to alter membrane potential during stimulation, imbalances of oxidative metabolism, and a diminished ability to withstand oxidant stress.[74] A complete discussion of neonatal PMN physiology is beyond the scope of this chapter, and only aspects that are particularly relevant to PMN transfusions and alternative therapies are reviewed here.

Neutropenia can occur during neonatal bacterial infections, particularly with fulminant sepsis. Because a physiologic neutrophilia occurs in normal neonates, it is considered quite abnormal for the absolute blood PMN count to fall below 3.0×10^9/L during the first week of life. Although an abnormally low PMN count can occur in neonates with disorders as diverse as sepsis, asphyxia, and maternal hypertension, suspicion of severe bacterial infection must always be high whenever relative neutropenia (PMN count, $<3.0 \times 10^9$/L) occurs. The mechanisms responsible are only partially defined, but abnormalities of neonatal granulopoiesis frequently are

involved. As one factor, the postmitotic marrow PMN storage pool (metamyelocytes and mature, segmented PMNs) is small. The PMN storage pool accounts for 26% to 60% of all nucleated cells in the bone marrow of normal neonates. Neonates with sepsis may exhibit a storage pool numbering less than 10% of nucleated marrow cells and are considered to have severely diminished marrow PMN reserves.[75] Second, storage pool PMNs are released at an excessively rapid and, apparently, poorly regulated rate from the marrow during stress. Third, PMN production in response to infection is decreased. The number of committed (clonogenic) PMN precursors in neonatal marrow is lower in neonates than in older patients, and a high percentage of these cells are proliferating even when studied at an apparently basal state.[75,76] Therefore, neonatal marrow is functioning at capacity and is unable to rapidly expand production to meet the increased demands of infection.[77] For this reason, it is logical to consider PMN transfusions until the marrow recovers.

Recommendations for Neutrophil Transfusions during Infancy

Because both quantitative and qualitative abnormalities of neonatal PMNs have been reported, PMN transfusions have been used to treat neonatal sepsis with or without neutropenia. Neonates exhibiting fulminant sepsis, relative neutropenia (PMN count, $<3.0 \times 10^9$/L during the first week of life or $<1.0 \times 10^9$/L thereafter), and a severely diminished PMN marrow storage pool (less than 10% of nucleated marrow cells being postmitotic PMNs) are at increased risk of death if treated only with antibiotics. Results of 11 studies[78–88] on the use of PMN transfusions to treat infected neonates, 6 of which were designed as controlled studies,[78–81,86,87] have been reported. The fact that four of the six controlled studies noted significant benefit from PMN transfusions is encouraging.[78–81] However, the controlled studies contained several experimental flaws.[89]

Because of these scientific imperfections, firm recommendations for the role of PMN transfusions in the treatment of neonatal sepsis cannot be made at this time. Guidelines for PMN transfusions are presented in Table 37–2. Although antibiotics are the key to successful treatment of neonatal sepsis, antibiotic therapy is not 100% successful, and attempts to bolster body defenses are warranted. PMN transfusions have not provided a complete answer; although they are efficacious for infants with neutropenia and fulminant sepsis,[89] only PMN transfusions obtained by automated leukapheresis have demonstrated effectiveness.[88,89] Moreover, in many instances, standard supportive care with antibiotics seems adequate. Each institution must assess its own experience with neonatal sepsis. If almost all infants survive without apparent long-term morbidity when treated only with antibiotics, PMN transfusions are unnecessary, and attention should be focused on prompt diagnosis and optimal antibiotic therapy. If the outcome of standard therapy is not optimal, alternative therapies such as PMN transfusions must be considered to improve the outlook.

Alternatives to Neonatal Neutrophil Transfusions

Not all neonatologists prescribe PMN transfusions. Their proper role has not been irrefutably established by controlled clinical trials. Moreover, the preparation of PMN concentrates by leukapheresis can be cumbersome and expensive, and the process of collecting and transfusing PMNs can pose risks for both neonates and donors. Accordingly, alternative therapies have been suggested. However, their efficacy has not been clearly established, their risks are only partially defined, and they require extensive study before they can be widely accepted. Two modalities that have been suggested are IVIG and myeloid cytokines or growth factors.

Most studies evaluating IVIG to prevent infections have found little or only modest benefit.[90–101] However, results are inconsistent. Only a few studies have suggested prophylactic benefit.[88–90] In contrast, several therapeutic studies have demonstrated a benefit from the addition of IVIG to antibiotics in the treatment of neonatal infections.[102–106] In a meta-analysis, studies of prophylactic IVIG were found to demonstrate only minimal benefit, whereas studies of therapeutic IVIG exhibited unequivocal benefit.[107] Overall, the data are insufficient to justify the routine use of IVIG in all preterm neonates to prevent or treat sepsis. However, modest "physiologic" doses (0.3 to 0.4 mg/kg) may lessen the severity of bacterial sepsis in newborns with very low birth weights, who are likely to be hypogammaglobulinemic as a result of extremely premature birth (i.e., before the major placental transport of immunoglobulin G has taken place). However, caution must be used when prescribing IVIG therapy to prevent or treat neonatal sepsis. IVIG therapy, particularly at high doses, can impair body defense mechanisms.[108–110]

To date, properly designed clinical studies of recombinant myeloid growth factors given to human neonates are limited. In a controlled study,[111] 42 neonates with presumed bacterial sepsis, recognized within the first 3 days of life, were randomly assigned to receive three doses of either G-CSF or a placebo. Although the outcome of sepsis was not reported, G-CSF induced a significant increase in the blood PMN count, an increase in the marrow PMN storage pool, and an increase in PMN membrane C3bi expression—the last being an indication of enhanced functional capability.

In a controlled study of granulocyte-macrophage colony-stimulating factor (GM-CSF) in premature neonates,[112] 20 premature neonates were randomly assigned within 72 hours after birth to receive either GM-CSF or a placebo for 7 days. GM-CSF increased the blood PMN count, the marrow PMN storage pool, and C3bi receptor expression. In addition, neonates receiving GM-CSF exhibited an increase in blood monocyte and platelet counts. The study was not designed to assess efficacy in the prevention or treatment of infections.

Two additional randomized clinical trials have been conducted to assess the efficacy of G-CSF and GM-CSF. Neither demonstrated clear clinical benefit. In the G-CSF trial, 20 infants with neutropenia and sepsis received either G-CSF (10 mg/kg/day) or placebo for 3 days.[113] Acknowledging that the number of study subjects was too small for definitive conclusions, the study authors noted that G-CSF did not significantly improve severity of illness, morbidity, or mortality. In a preliminary report of the GM-CSF trial,[114] preterm infants received either GM-CSF (8 µg/kg/day) or placebo for the first 28 days of life in an attempt to reduce the incidence of infections. Although GM-CSF was well tolerated and significantly increased blood leukocyte counts, it did not significantly decrease infection rates. Therefore, firm guidelines cannot be made at this time regarding the proper role of myeloid growth factors in the management of neonatal neutropenia or sepsis.

Clearly, there is no universally accepted role for PMN transfusions, IVIG, or myeloid growth factors in the treatment of neonatal sepsis. However, it seems reasonable to

treat fulminant sepsis in neonates with neutropenia (blood PMN counts $<3 \times 10^9$/L during the first week of life or $<1 \times 10^9$/L thereafter) as follows. For infants born before 30 weeks' gestation, give one dose of 500 mg/kg of IVIG plus 5 µg/kg of G-CSF on 3 consecutive days. For infants born at 30 weeks' gestation or later, give 5 µg/kg of G-CSF on 3 consecutive days. This therapy should be adjunctive to optimal antibiotic and supportive care.

PLASMA PRODUCT TRANFUSIONS

Recommendations for use of plasma product transfusions do not need to be broken down into sections for older children and adolescents and infants and younger children because product selection is similar in each group and in adults. However, due to smaller plasma volumes in many of these individuals, certain aspects need to be emphasized. First, plasma (all types) should be ABO-compatible with the recipient's RBCs; in other words, it should not contain donor isohemagglutinins that may react with the recipient A and/or B red cell antigens. This is to prevent a "minor side" ABO incompatibility that could result in an acute hemolytic transfusion reaction, which has a higher probability of occurring in a smaller patient receiving "out-of-group" plasma.[66,115] When considering the patient's RhD status, FFP is usually not matched because it contains very low numbers of RBCs. However, when large volumes of RhD-positive FFP (>20 mL/kg) are being transfused to RhD-negative pediatric patients (or women of childbearing age), RhD immunization prevention with RhD immune globulin should be considered.

Frozen Plasma

Recommendations with regard to blood component administration and guidelines for transfusion of FFP, plasma frozen within 24 hours F24, and cryoreduced plasma have been recently published for neonates and pediatric patients.[1,116] The indications and contraindications are very similar for neonates and pediatric patients as for adults; however, dosing is in mL/kg rather than units. The dose of FFP in children is 10 to 20 mL/kg (Table 37–5). This dose will raise most coagulation factor levels by approximately 20%.[117] However, plasma frozen within 24 hours has lower levels of factor VIII and factor V and thus might not increase those factors as high as 20%.[118] Generally, this is not of clinical significance, and FFP and plasma frozen within 24 hours are used interchangeably. On the other hand, cryoreduced plasma (devoid of factor VIII, von Willebrand factor, factor XIII, and fibrinogen) was recently approved by the U.S. Food and Drug Administration for use in refractory thrombotic thrombocytopenic purpura (TTP), those patients who are unresponsive to standard therapy with FFP, as its only true indication. Some authorities advocate the use of cryoreduced plasma as a first-line therapy for TTP, an off-label use. However, in 2001 the North American TTP Group published a multicenter prospective, randomized trial comparing exchange transfusion with FFP to cryoreduced plasma for the initial treatment of TTP. They demonstrated that survival was the same in both study groups and concluded equal efficacy between FFP and cryoreduced plasma for initial therapy in TTP.[119,120]

Reference values of plasma concentrations for each coagulation factor for pediatric patients under age 6 months are lower than for children and adults with regard to vitamin K–dependent factors (factors II, VII, IX, and X) in addition to the contact factors and the vitamin K–dependent natural inhibitors of coagulation. As a result the prothrombin time and activated partial thromboplastin time are prolonged. This distinct difference should be taken into account when considering frozen plasma therapy for prolonged screening tests in children under age 6 months who are septic with disseminated intravascular coagulation and hemorrhage from surgery or trauma, because these already low factors may be depleted due to lower baseline levels initially and may warrant earlier intervention with plasma transfusion.[121] Another important point regarding frozen plasma is that it is not indicated for volume expansion nor for improving wound healing.[1,122]

Table 37-5 Guidelines for the Dosing and Transfusion of FFP/F24/CRP and Cryoprecipitate

Fresh Frozen Plasma (FFP)/Plasma Frozen in 24 hr (F24)/Cryoprecipitate Reduced Plasma (CRP)

Dosing: 10–20 mL/kg to achieve approximately 20% rise in factor levels (assuming 100% recovery)

Indications:

1. Supportive care during disseminated intravascular coagulation management
2. Replacement therapy
   a. Factor replacement when concentrates not available (e.g., antithrombin III and protein S deficiencies, and factors II, V, X, and XI deficiencies)
   b. Therapeutic plasma exchange when FFP/F24/CRP is indicated
3. Warfarin reversal in emergency situations (e.g., prior to invasive surgical procedure with active bleeding)

Cryoprecipitate

Dosing: 1–2 units/10 kg body weight to increase fibrinogen by 60–100 mg/dL (assuming 100% recovery)

Indications:

1. Hypofibrinogenemia or dysfibrinogenemia with active bleeding
2. Hypofibrinogenemia or dysfibrinogenemia prior to invasive procedure
3. Factor XIII deficiency with active bleeding or prior to invasive procedure
4. vWD and hemophilia A with active bleeding and no plasma-derived factor vWF/FVIII concentrate available and no recombinant FVIII product available, respectively
5. Uremic bleeding
6. Fibrin glue sealant preparation

Adapted from Roseff SD, Luban NLC, Manno CS. Guidelines for assessing appropriateness of pediatric transfusion. Transfusion 2002;42:1398.

CRYOPRECIPITATE

Just as with the various types of frozen plasmas available, the indications for cryoprecipitate transfusion are the same in children as in adults. Again, in children it is recommended to give ABO-compatible units; however, the RhD group need not be honored. The dose is approximately 1 to 2 pooled units for every 10 kg of body weight. Table 37–5 outlines the dosing and indications for transfusion of cryoprecipitate. In neonates and pediatric patients cryoprecipitate is mostly administered to increase fibrinogen. It is rarely transfused in the United States for von Willebrand's disease or factor VIII deficiency because safer products are recommended, such as virally inactivated and recombinant factor VIII products.[123]

Chapter 38

Transfusion of the Hemoglobinopathy Patient

Krista L. Hillyer • James R. Eckman

SICKLE CELL DISEASE

Pathogenesis and Clinical Pathology

Eight percent of African Americans are heterozygous carriers of hemoglobin S (HbS), and 1 in every 300 has sickle cell disease (SCD). The homozygous state (HbSS), also known as *sickle cell anemia,* is the most common type of SCD in the United States; 1 in 600 African Americans has HbSS.[1,2] Compound heterozygote states, such as sickle cell hemoglobin C (HbSC) disease, together with the combination of HbS and β-thalassemia (sickle cell/β-thalassemia), account for most of the remaining African American cases of SCD.[1,2] Other types of SCD arise from the interaction of HbS with rarer hemoglobin variants; these account for a small number of SCD cases in North America.

Patients with SCD have HbS levels greater than 50% of the total hemoglobin (Hb) concentration. This abnormal sickle hemoglobin, when deoxygenated, forms polymers within the erythrocyte that distort its shape and decrease its deformability, leading to vaso-occlusive phenomena. A detailed description of the molecular pathogenesis of SCD is beyond the scope of this text; the reader is referred to Bunn[3] and Steinberg[4] for recent extensive reviews of this topic.

The vaso-occlusive events, abnormal blood rheology, complex cellular interactions, and other poorly understood factors resulting from the polymerization of HbS cause hemolytic anemia and increased susceptibility to infection, infarctive organ damage, and recurrent episodes of severe pain (Table 38–1). As a result of these complications, patients with HbSS have a reduced life span.[5] Many of the complications of SCD can be abrogated, ameliorated, or prevented by transfusion of donor red blood cells (RBCs). Because of the numerous proven clinical benefits from transfusion and the complex rheologic properties of sickle blood, there are a number of unique goals, indications, and methods for transfusion in SCD.

Goals of Transfusion Therapy

The goals of RBC transfusion in SCD patients are: to improve oxygen-carrying capacity by increasing the total Hb concentration; to decrease blood viscosity and improve blood flow by diluting RBCs containing sickle hemoglobin; and to suppress endogenous erythropoiesis by increasing tissue oxygenation.[6] The first goal is common to many clinical indications for RBC transfusion. The latter two goals for RBC transfusion are required only in individuals with hemoglobinopathies. They also provide unique potential benefits, as well as associated complications, when compared with standard methods of transfusion.

Methods of Transfusion Therapy

Unique Transfusion Considerations in Sickle Cell Disease

Several methods of RBC transfusion therapy are used for SCD patients (Table 38–2) because of the potential limitations of acute simple transfusions, including acute volume overload and reduction in blood flow from increased blood viscosity.[7] Patients with SCD have normal or increased total blood volume because plasma volume is increased in response to chronic anemia. Acute increases in total blood volume after transfusion of RBCs may increase cardiac work to the point of precipitating congestive heart failure.

Perhaps a more important consideration in SCD relates to changes in blood viscosity from the transfusion of RBCs.[8] Viscosity of deoxygenated or oxygenated sickle blood is increased, when compared with normal blood at any hematocrit (Hct).[7]

Because of the opposing effects of Hct on oxygen content and blood viscosity, the optimal Hct is approximately 40% for normal arterial blood. The optimal Hct for sickle blood is strongly dependent on oxygen tension, varying from 18% at a PO_2 of 18 mmHg to 31% for fully oxygenated arterial blood.[7]

Transfusion of normal RBCs significantly increases sickle blood viscosity when the proportion of HbS-containing cells is greater than 60%.[7] The increase in viscosity is minimal when the proportion is less than 40%.[7]

These in vitro observations translate into clinically relevant reductions in tissue oxygenation in SCD patients who are transfused to a Hct greater than 30%. This forms the rationale for the use of acute exchange transfusion in many sickle complications.[8] Chronic erythrocytapheresis is primarily used to decrease iron overload.[8]

Acute Simple Transfusion

In *simple transfusion*, normal donor RBCs are infused into the patient without removal of the patient's own RBCs. In general, acute simple transfusion is indicated when the immediate need for oxygen-carrying capacity is increased but there is no need for a dramatic decrease in the percentage of HbS in the patient's blood.[9] The volume of RBCs to be transfused can be calculated by the formula shown in Figure 38–1.

Erythrocytapheresis (acute and chronic)
Manual red blood cell exchange transfusion

When transfusing patients with SCD, it is desirable to maintain the Hct at 30% or less. Once the Hct rises above 30%, oxygen delivery to the tissues may decrease, owing to increases in viscosity.[10] Because the primary goal of RBC transfusion is to rapidly improve oxygen delivery to tissues to prevent ongoing ischemia, the maximum beneficial Hct to be achieved by transfusion is 30%.

For simple transfusion, donor RBCs may be infused through an 18- to 23-gauge needle or catheter, depending on the size of the patient and the accessibility of his or her peripheral veins, using a standard blood infusion set.[11]

Chronic Simple Transfusion

Chronic simple transfusion is indicated for a variety of clinical situations in which it is desirable to increase oxygen-carrying capacity and to chronically depress the percentage of HbS in the patient's blood.[9] When a specific decrease in HbS percentage is desired, the calculation shown in Figure 38–2 estimates the dilutional effects of transfusion on HbS.

As for acute simple transfusion, the typical goal of chronic transfusion therapy is to maintain the HbS percentage at less than 30% of the total Hb concentration.[9,12] In average-size adults, maintenance of less than 30% HbS usually requires transfusion of 2 to 3 units of RBCs every 3 to 5 weeks. For children, the amount may be calculated from the formula in Figure 38–2. The total volume of RBCs to be transfused at each regular interval in a chronic simple transfusion protocol is determined by the pretransfusion level of hemoglobin A (HbA). If the HbA percentage is too low (in most cases, 70% HbA or higher is the goal), either the volume of RBCs to be transfused is increased or the time interval between transfusions is decreased.

In the case of chronic simple RBC transfusion therapy, catheters may be surgically implanted and used for multiple transfusion events. This allows for improved venous access and less patient discomfort. Peripheral veins may also be used for chronic transfusion.

Red Blood Cell Exchange Transfusion (Manual and Automated)

Donor RBCs are infused while the patient's own RBCs are removed simultaneously in the method of transfusion known as *RBC exchange therapy*. The major benefits of RBC exchange are the rapid adjustments in the patient's Hct and HbS levels. This is a critically important factor during acute sickling episodes, the major indication for RBC exchange; during certain acute ischemic episodes, the replacement of sickled RBCs with normal donor RBCs (improving oxygen delivery to ischemic tissues) must be accomplished quickly to prevent further tissue damage.[9] In addition, unlike simple transfusion, RBC exchange allows for removal of the same volume of RBCs as is replaced, decreasing the risk of iron overload associated with chronic simple transfusion.

The usual measurable end points of RBC exchange therapy are: HbA level of 70%; HbS level of 30%; and overall Hct of 30% or less.[13] The Hct is maintained at 30% or less to achieve balance of viscosity.

Red blood cell exchange transfusion is typically performed with the use of an automated apheresis instrument (erythrocytapheresis). This instrument removes the patient's blood, separates the RBCs from the platelet-rich plasma by

Figure 38–2 Volume of red blood cells (RBCs) to be transfused to sickle cell patients using the chronic simple transfusion method. HbS, sickle hemoglobin; Hct, hematocrit; TBV, total blood volume. (From Wayne AS, Kevy SV, Nathan DG. Transfusion management of sickle cell disease. Blood 1993;81:1109–1123.)

centrifugation, returns the plasma to the patient, and discards the patient's sickled RBCs. At the same time, donor RBCs are infused, maintaining a stable blood volume throughout the procedure. In the past, RBC exchange transfusion could be performed only manually, and a variety of formulas were used to estimate the appropriate exchange volumes. Today, indications still exist for manual RBC exchange, but erythrocytapheresis is currently the most common method of RBC exchange.

The automated apheresis instrument has an internal programmable computer that precisely calculates both the volume of the patient's RBCs to be removed and the volume of the donor's RBCs to be infused. First, the patient's total blood volume and RBC volume are calculated by entering into the computer the patient's gender, height, weight, and current Hct. Next, the desired HbS percentage, the desired final Hct, and the Hct of the donor RBC preparation are entered, and the appropriate volumes for exchange are determined. However, the formula shown in Figure 38–3 provides a general, practical estimate of the number of RBC units to be used in automated RBC exchange transfusion. Having an estimate of the number of units to be exchanged before initiation of the procedure is important, because the blood bank may need extra time to procure the appropriate RBC units.

The process of erythrocytapheresis is as follows. In most cases, central venous access is established, typically in the subclavian vein or the internal jugular vein, using a hemodialysis-grade, rigid-wall, large-lumen, double-bore catheter that can withstand high flow rates. In adults and larger children with easily accessible peripheral veins, the antecubital veins may be acceptable for use, with 16- to 18-gauge needles used for blood removal and 18- to 20-gauge catheters for blood return. The apheresis instrument, after being programmed with the appropriate patient data and the desired end points for therapy, is used by a trained operator to remove the patient's RBCs and replace them with donor RBCs. Of note, it is usually desirable to replace the patient's sickled RBCs with HbS-negative (sickle trait–negative) donor RBCs in an exchange procedure, for the purposes of appropriately calculating and achieving the desired percentages of HbS and HbA.[12] However, if HbS-negative units cannot be procured in a timely manner, it is at the clinician's discretion (dependent on the severity and acuteness of patient illness) whether or not to wait for HbS-negative units to be identified.

In infants and small children, the amount of blood in the extracorporeal circuit of the automated apheresis machine represents a significant percentage of the child's total blood volume, which may lead to hypotension or a critically low Hct, or both, if the machine is primed with saline. Instead, the automated apheresis instrument should be primed with RBCs if the extracorporeal circuit represents 12% or more of the child's blood volume, the child weighs less than 20 kg, or the child is anemic or unstable.[13]

$$\text{Exchange RBC volume (mL)} = \text{desired \% Hct} \times \text{TBV}$$

Figure 38–3 Practical estimate of the volume of red blood cells (RBCs) to be transfused to sickle cell patients using the automated RBC exchange transfusion method. Hct, hematocrit; TBV, total blood volume. (From Wayne AS, Kevy SV, Nathan DG. Transfusion management of sickle cell disease. Blood 1993;81:1109–1123.)

Occasionally, certain patients require manual RBC exchange transfusions. Manual RBC exchange may be necessary in infants who have very small total blood volumes and in emergencies involving children or adults, when the additional time required to establish appropriate venous access or to mobilize the apheresis team would be deleterious to the patient's health. A rapid manual partial RBC exchange may be performed by withdrawing blood from a peripheral (usually antecubital) vein and infusing RBCs via a stopcock into the same vein (or directly into a different peripheral vein), using the methods outlined in Table 38–3. The requirements that must be honored to ensure a safe and effective manual exchange transfusion are the following: marked increases in blood viscosity should be avoided; blood volume should be maintained throughout the exchange; and the exchange should be completed in the shortest length of time possible.[14] These three important factors must be evaluated and balanced, based on the unique clinical circumstances of the individual patient in need of exchange transfusion.

SELECTION OF ANTICOAGULANT/PRESERVATIVE SOLUTIONS

In the past, when RBC units were collected primarily in citrate-phosphate-dextrose (CPD) or citrate-phosphate-dextrose-adenine (CPDA-1) solutions, these units were reported to have average hematocrits of 80% or more, and it was recommended that RBCs be "reconstituted" to the volume and Hct of whole blood (30% to 40%) by adding albumin or saline to the blood bag or syringe before manual exchange transfusion to the SCD patient.[14]

However, the current average Hct of an RBC unit is approximately 50% to 70%,[11,15] whether collected in CDPA-1 solutions or in additive systems (e.g., AS-1, AS-3) that extend the shelf life of the product. The alternating administration to an SCD patient of RBCs and saline in equal volumes (see Table 38–3) should theoretically deliver a product essentially identical to "reconstituted" whole blood.

Red blood cells containing additive solutions have more adenine and/or mannitol, in comparison with CPD or CPDA-1–preserved RBC units, depending on the type of additive solution used. Some clinicians hesitate to transfuse RBC units with additional mannitol and adenine, in response to case reports of renal toxicity and significant fluid shifts, in neonates given large volumes of these substances. In a comprehensive review of the existing literature, Strauss concluded that small-volume transfusions of RBCs stored in additive solutions administered to neonates do not lead to an increased risk of adverse events.[16] In the setting of large-volume transfusions, such as RBC exchanges, existing literature does not support or disavow the use of RBCs stored in additive solutions. Thus, many clinical protocols choose to utilize RBC units stored in

Table 38-3 Method for Rapid Manual Red Blood Cell (RBC) Exchange Transfusion in Sickle Cell Patients, Using Practical Exchange Volume Estimates, for Children and Adults.

Children

1. Calculate exchange volume, using 60 mL/kg as a practical estimate.
2. Divide the calculated exchange volume of RBCs into four equal aliquots.
3. Withdraw blood from the patient equal to one exchange aliquot.
4. Infuse saline equal to one exchange aliquot.
5. Withdraw blood from the patient equal to one exchange aliquot.
6. Transfuse a volume of RBCs equal to two exchange aliquots.
7. Repeat steps 3-6.

Adults

1. The exchange volume is 6–8 RBC units, depending on the size of the patient (an average 70-kg man requires approximately 6 RBC units).
2. Withdraw 500 mL of blood from the patient.
3. Infuse 500 mL of saline.
4. Withdraw 500 mL of blood from the patient.
5. Transfuse two units of RBCs.
6. Repeat until 6–8 RBC units have been transfused.

RBC units and saline infused in this alternating manner should theoretically deliver a blood product that is essentially "reconstituted" (within the patient) to the volume and hematocrit of whole blood (30% to 40%), because the current estimated average hematocrit of an RBC unit is 50% to 70%.[60,130] However, if a known exact percent hematocrit of the blood product to be infused is desired, RBCs may be reconstituted to the volume and hematocrit of whole blood (30% to 40%) within a blood bag or syringe, by the addition of saline or other diluents.[131] (From Reid CD, Charache S, Lubin B (eds). Management and Therapy of Sickle Cell Disease, 3rd ed. Bethesda, Md., National Institutes of Health Publication No.99-2117, 1999, p 62.)

CPDA-1 solution for large-volume transfusions in neonates, particularly if these children have liver or kidney dysfunction that would put them at risk for adverse events.

In addition, the amount of potassium transfused to neonates is of concern to clinicians, because mortality following transfusion of RBCs with high potassium levels has been reported.[17] As the shelf life of RBC units is extended, potassium is known to leak from the RBCs, although in amounts that are typically easily processed by individuals with normal kidney function. However, in large-volume and RBC exchange transfusions, many transfusion protocols for SCD patients recommend (but do not require) the use of RBC units that are 7 days old or less. This general practice of transfusing "young" RBC units to SCD patients is of practical use as well, in that younger RBCs will remain in the circulation of the patient for a longer period than will older RBCs.

Chronic Erythrocytapheresis (Automated Red Blood Cell Exchange)

Iron overload is one of the serious long-term complications of chronic transfusion in SCD patients.[18] As a result, certain investigators[19–23] have suggested that *chronic erythrocytapheresis* should be used in place of chronic simple transfusion for the prevention of complications of SCD and to decrease long-term iron accumulation in these patients.

The procedure for chronic erythrocytapheresis is the same as that for acute erythrocytapheresis. Similarly, target postpheresis HbS levels for chronic erythrocytapheresis are usually less than 30%, with desirable postpheresis hematocrits of 30% or less. Currently, chronic erythrocytapheresis is not universally used in the United States for SCD patients, although recent reports suggest that the potential benefits of this method may outweigh its risks and costs. A detailed review of the current literature regarding the role of chronic erythrocytapheresis is provided later in this chapter (see "Iron Overload").

Indications for Transfusion Therapy

RBCs may be administered to patients with SCD by simple RBC infusion or by RBC exchange, either episodically, for the relief of acute symptoms, or chronically, for the prevention of long-term complications. A summary of indications for transfusion of RBCs in SCD patients is shown in Table 38–4. These indications are characterized in the following sections as *generally indicated* or *controversial,* based on several recently published reviews of of the work of various sickle cell experts.[13,24]

Indications for Episodic Transfusion

ACUTE SYMPTOMATIC ANEMIA

Because patients with SCD are chronically anemic, they are often asymptomatic despite very low Hb levels. Biochemical and physiologic factors that decrease symptoms during chronic anemia include increased levels of 2,3-diphosphoglycerate, decreased oxygen–Hb affinity, increased plasma volume, and increased cardiac stroke volume and output.[25] Patients may become acutely symptomatic, making simple transfusion necessary, if they experience a rapid decrease in Hb, hypoxia, or acute cardiac decompensation. Acute anemia can result from bleeding, suppression of erythropoiesis by infection, sequestration, or increased hemolysis. Pulmonary or cardiac disease can cause decompensation, requiring acute transfusion to increase the Hb level above the patient's stable baseline.

APLASTIC CRISIS

Aplastic crisis, typically defined as a decrease in Hb of more than 3.0 g/dL with reticulocytopenia, is a relatively common occurrence in SCD.[26] Aplastic crisis occurs in SCD patients after marked suppression of erythropoiesis for 7 to 10 days, usually as a result of infection of RBC precursors in the bone marrow by human parvovirus B19. In a sample group of 308 children with SCD, human parvovirus B19 accounted for all cases of aplastic crisis that occurred during an 8-year observation period.[27] Because mean RBC survival time in many SCD patients is only 12 to 15 days, the acute life-threatening anemia caused by human parvovirus B19 infection necessitates immediate RBC transfusion to sustain oxygen delivery to the tissues until the bone marrow recovers. Simple RBC transfusion is usually administered slowly (1 mL/kg/hr), because these patients have expanded plasma volumes due to chronic anemia and care must be taken to avoid volume-induced congestive heart failure.[8,28] Partial exchange transfusion, performed by manually removing whole blood and returning RBCs to the patient without replacing the plasma, may be preferred if heart failure from acute volume overload is of significant concern.[9]

ACUTE CHEST SYNDROME

According to a report by the Cooperative Study of Sickle Cell Disease, acute chest syndrome occurs at least once

Table 38–4 **Clinical Indications for Transfusion in Patients with Sickle Cell Disease**

Type of Transfusion	Indication	Controversial Indications	Nonindications
Episodic	Acute symptomatic anemia	Acute painful episode (acute pain crisis)	Normal pregnancy
	Transient red cell aplasia ("aplastic crisis")	Acute priapism	
	Acute chest syndrome	Preparation for infusion of contrast media	
	Hyperhemolysis		
	Acute splenic sequestration		
	Acute hepatic sequestration		
	Stroke		
	Prior to surgery requiring general anesthesia		
	Prior to eye surgery		
	Acute multiorgan system failure		
	Severe infection with concurrent severe anemia		
Chronic	Prevention of recurrent strokes in children	Recurrent priapism	Leg ulcers
	Prevention of first stroke in children	"Silent" cerebral infarcts	Growth and developmental delays
	Complicated pregnancy	Neurocognitive defects	Early retinopathy
	Chronic hypoxic lung disease	Recurrent acute chest syndrome	Early renal disease
	Frequent severe pain episodes	Prevention of pulmonary hypertension/cor pulmonale	
	Chronic heart failure		
	Chronic renal failure		

in approximately 30% of SCD patients, and half of these patients will experience one or more recurrent episodes.[24] Acute chest syndrome is the second most common reason after infection for hospital admission among SCD patients,[29,30] and it is responsible for 25% of all deaths in this population.[31]

Transfusion therapy is vital to the treatment of acute chest syndrome early in its course,[32] and exchange transfusion has been shown to result in rapid improvement of acute chest syndrome if instituted within 48 hours after diagnosis.[33] Simple transfusion causes dramatic improvement of symptoms in children with acute chest syndrome (compared with nontransfused children) if it is begun within 24 hours after diagnosis[34]; therefore, in patients with less serious compromise, simple transfusion is preferred.[35] For those patients with either a progressive decline in arterial oxygen pressure (Pao_2 <60 mm Hg in adults, <70 mm Hg in children) or a rapid clinical deterioration, RBC exchange transfusion is recommended.

ACUTE SPLENIC OR HEPATIC SEQUESTRATION

Acute splenic sequestration occurs in SCD patients when sickled RBCs are trapped within splenic sinusoids. As the spleen enlarges, it traps a significant proportion of the circulating RBCs, leading to increased anemia and circulatory failure.[36] The fatality rate from acute splenic sequestration approaches 10%, and approximately 50% of those who survive a first episode will experience another.[36] Immediate simple RBC transfusion has been shown to produce rapid resolution of acute splenic sequestration.[36,37] Splenic sequestration occurs in HbSS patients early in life. It occurs less frequently, but at all ages, in patients with HbSC or sickle cell/β-thalassemia.

Older patients may develop acute hepatic sequestration, which responds well to a similar transfusion strategy.[38]

ACUTE STROKE

Approximately 3.75% of patients with SCD will experience one or more cerebrovascular accidents, according to a longitudinal clinical trial published by the Cooperative Study of Sickle Cell Disease in 1998.[39] The occurrence of infarctive stroke is greatest in children and older patients, whereas the occurrence of hemorrhagic stroke is greatest in patients 20 to 29 years of age. Because the neurologic sequelae of strokes are often devastating, immediate RBC exchange transfusion is indicated upon diagnosis of stroke.[13] Dramatic recovery of neurologic function has been documented after exchange therapy in SCD patients with acute stroke.[39,40]

The stroke prevention trial in sickle cell anemia (the STOP study)[41] identified children who were at high risk for stroke based on elevated cerebral blood flow, as measured by transcranial Doppler (TCD) screening tests. The STOP study also showed that children at high risk for stroke who received intermittent simple transfusions (chronic RBC transfusions) had a 90% relative decline in stroke rates during the transfusion study period, as compared with children at risk for stroke who did not receive intermittent simple transfusions. The many informative results of the STOP study[41,42] have led to the general implementation of chronic simple RBC transfusion in children at high risk for stroke as measured by TCD (see discussion in "Indications for Chronic Transfusion").

Transfusion in the Perioperative Period

BEFORE SURGERY REQUIRING GENERAL ANESTHESIA

Hypoxia, volume depletion, hypotension, hypothermia, and acidosis are all complications of general anesthesia that can lead to intravascular sickling and vascular occlusion, resulting in high rates of morbidity and mortality among SCD patients

undergoing general anesthesia.[43] In a prospective study of 717 SCD patients, including 1079 surgical procedures, those patients undergoing low-risk surgeries who received perioperative RBC transfusions had a 4.8% rate of SCD-related postoperative complications, compared with a significantly higher complication rate of 12.9% among similar patients who were not transfused.[44] For minor procedures and tonsillectomies, many patients did not receive transfusions and complication rates were very low.[44] Similarly, in a prospective trial of 364 SCD patients undergoing cholecystectomy, the most common surgical procedure among pediatric and adult SCD patients,[44] those who were not transfused perioperatively had a higher incidence of sickle cell events (32%) than transfused patients did.[45]

In a controlled, randomized trial, Vichinsky and colleagues[43] compared "aggressive" versus "conservative" transfusion regimens in the perioperative management of 604 operations in 551 patients with SCD. The aggressive transfusion regimen was designed to maintain a preoperative Hb level of 10 g/dL and an HbS level at or below 30%. The conservative transfusion regimen only maintained a preoperative Hb level of 10 g/dL, regardless of the percentage of HbS. Results showed that the frequency of serious perioperative complications was similar in the aggressive and conservative transfusion groups (31% and 35%, respectively), whereas the transfusion-related complication rates were 14% and 7%, respectively. The authors concluded that a conservative transfusion regimen is as effective in preventing perioperative complications as an aggressive transfusion regimen.

Conversely, Adams and associates[42] published a retrospective review of 92 children with SCD who underwent 130 surgical procedures using an aggressive transfusion regimen, with most RBC units phenotypically matched to recipients for Rh and Kell antigens. Major perioperative complications occurred in only 12% of surgical procedures, compared with 31% to 35% in Vichinsky's study.[43] The transfusion-related complication rate in Adams' pediatric study (8%) was similar to the rate observed in the conservative arm of Vichinsky's adult and pediatric study (7%). Although Adams suggested that the more aggressive approach with phenotypically matched blood is superior, it is difficult to directly compare the results of this small, retrospective study with those of a large, randomized, controlled clinical trial.

For adults and pediatric patients with SCD who are to undergo general anesthesia, current National Institutes of Health guidelines recommend simple transfusion to increase the preoperative Hb level to 10 g/dL, together with intraoperative or postoperative RBC replacement for blood loss,[46] a position supported by a recent Cochrane Database Review, which concluded that recommendations regarding optimal use of RBC transfusions prior to surgery cannot be adequately assessed at this time and require further study.[47]

BEFORE EYE SURGERY

The use of transfusions in patients undergoing eye surgery is controversial. Although early studies advocated the use of aggressive exchange transfusion for patients undergoing retinal or vitreous surgery, more recent studies have documented that this approach may not be necessary.[48]

Although eye surgery is typically performed under local anesthesia, the microvascular nature of the surgery and the importance of avoiding permanent damage to the eye justify the use of blood transfusion for this indication. Until further data are available, it is reasonable to follow guidelines similar to those used for transfusion of SCD patients undergoing surgical procedures performed under general anesthesia.

ACUTE MULTIORGAN FAILURE SYNDROME

Acute multiorgan failure syndrome may occur after some episodes of severe pain crisis in SCD patients and affects at least two of the following three organs: lung, liver, or kidney. Immediate initiation of RBC transfusion is recommended for the treatment of acute multiorgan failure syndrome.[13,49] Dramatic clinical improvement and rapid reversal of organ dysfunction have been observed after prompt, aggressive transfusion therapy. Simple transfusion is indicated for patients with severe anemia and rapidly falling Hb levels. Exchange transfusion is indicated for those with higher Hb levels or more severe organ failure.[49]

SEVERE INFECTION

Bacterial and malarial infections are common, life-threatening complications occurring in SCD patients worldwide. Some experts do consider it acceptable medical practice to transfuse individuals with severe anemia who have concomitantly serious infections.[13] Infection without concomitant anemia is not a widely accepted indication for transfusion in SCD patients.

Indications for Chronic Transfusion

PREVENTION OF RECURRENT STROKES IN CHILDREN

Approximately 3.75% of SCD patients will experience one or more cerebrovascular accidents, or strokes.[39] Without therapeutic intervention, strokes will recur in more than two thirds of this patient group within 2 to 3 years.[50] Chronic RBC transfusions provide a reduction of up to 90% in the risk of recurrent stroke in these SCD patients (10% risk of recurrent stroke while undergoing a chronic RBC transfusion regimen).[41,46,47,51,52]

The chronic simple transfusion regimen recommended for prevention of recurrent stroke, in the 3.75% of SCD patients who have experienced a stroke, is simple RBC transfusion every 3 to 4 weeks, with a goal of maintaining HbS at less than 30% and Hct at 30% or less.[41,46,47,51,53]

In a small group of patients in whom the desired HbS level was modified to 50% after they had been neurologically stable for 3 years, Cohen and colleagues[54] reported no increased risk of recurrent stroke with chronic transfusion maintaining a 30% HbS level. The major benefit of this modified regimen was a 31% decrease in blood requirements for simple transfusions, which reduced cost, decreased inconvenience, and mitigated the development of alloimmunization and iron overload. Although the sample size was too small to conclude that this method is absolutely effective at preventing recurrent stroke, some experts allow the HbS percentage to increase to 50% in patients who have been stable neurologically for 3 years with chronic transfusion.[13] However, the most widely used guideline is to maintain HbS levels at or below 30% for those SCD patients on a chronic simple transfusion protocol for stroke prevention.

The optimal duration of chronic transfusion for prevention of recurrent stroke is not known, although much productive and informative research has been recently published in this regard.[55] In the 1990s, Wang and coworkers[56] reported that 5 of 10 patients had recurrent strokes within 1 year after discontinuation of chronic transfusions, after a median period without recurrence (since first stroke) of 9.5 years. This rate was significantly greater than the 10% estimated

risk of recurrent stroke among patients receiving chronic transfusion therapy. Therefore, most centers since that time have recommended continuation of chronic transfusion therapy indefinitely to prevent recurrent stroke.[13,54]

The Stroke Prevention Trial II (STOP-II) was begun in 2000, with the intention of determining the optimal duration of RBC transfusion therapy in SCD children at risk for first stroke based on TCD screening. This study was halted 2 years early, because the study showed that there was clear evidence of return to high risk of stroke (and stroke itself) in that group of children randomly assigned to the "stop transfusion" group. No such risk was seen in the "continue transfusion" group.[55]

Although the intention of STOP-II was to investigate the outcomes of halting transfusions in children at risk for first stroke, the results can be extrapolated to those children with SCD who have already experienced one or more strokes. Thus, for those children with SCD who have experienced one or more strokes, it is recommended that chronic transfusion protocols be continued indefinitely to prevent recurrent strokes.

PREVENTION OF FIRST STROKE IN CHILDREN

High blood flow velocity in the internal carotid and middle cerebral arteries, detected by TCD, has been found to be predictive of subsequent stroke in children with SCD.[57,58] Adams and associates[42] used TCD to identify children at high risk for stroke, randomly assigned them to receive either standard care or chronic transfusion therapy, and then compared the incidence of stroke between the two groups. There were 11 strokes in the standard-care group but only 1 stroke in the transfusion group, a 92% difference in the risk of stroke ($p < 0.001$). The authors concluded that transfusion greatly reduces the risk of first stroke in children with SCD who have abnormal TCD results.[42] Because this diagnostic method is safe and noninvasive, and the prevention of stroke in these patients can greatly reduce the morbidity and mortality of this complication, many sickle cell centers have implemented regular TCD screening and subsequent chronic transfusion in children with repeated high flow rates, in order to prevent first strokes in children with SCD.[13,24]

The Stroke Prevention Trial II was begun in the year 2000. STOP-II was a multicenter, randomized clinical trial, the intention of which was to determine the optimal duration of RBC transfusion therapy in children with SCD at risk for first stroke, based on TCD screening.[55] The hypothesis of the investigators was that regular RBC transfusions might be safely stopped following (at minimum) 30 months of transfusion therapy, for those children with SCD at high risk for stroke.

The trial was halted by the National Heart, Lung, and Blood Institute (NHLBI) 2 years early, in November 2004, after 79 patients had been enrolled, because 14 of the 41 patients in the group who stopped regular RBC transfusions after a minimum of 30 months reverted to a high risk of stroke, as measured by TCD screening. Two of these children actually suffered strokes. In contrast, of the children who were randomly assigned to the group that are continued transfusions after 30 months, none had strokes or reversions to high risk of stroke. Therefore, the NHLBI issued a clinical alert to physicians in December 2004 that stated that stopping RBC transfusions in SCD pediatric patients at high risk for stroke could not be recommended.

Thus, at this time, it is recommended that children at high risk for stroke should continue on chronic transfusion protocols indefinitely to reduce the risk of first stroke.

COMPLICATED PREGNANCY

Although normal pregnancy in SCD patients is not an indication for prophylactic transfusion,[59–61] certain complications of either the pregnancy itself or the underlying disease process are indications for simple or exchange transfusion (see Table 38–1). These include preeclampsia/eclampsia, twin pregnancy, previous perinatal mortality, acute renal failure, sepsis, bacteremia, severe anemia with reduction in Hb of more than 20% from baseline or an Hb concentration lower than 5 g/dL, acute chest syndrome, hypoxemia, anticipated surgery, and preparation for infusion of angiographic dye.[62]

For all of these indications, simple transfusion is most often used if the Hb concentration is lower than 5 g/dL and the reticulocyte count is less than 3%. If the Hb is 8 to 10 g/dL or greater, exchange transfusion is indicated, with the goal of a post-transfusion Hb concentration of 10 g/dL and a post-transfusion HbS of 50% or less.[63]

CHRONIC ORGAN FAILURE

Patients with renal failure develop progressive anemia because of the loss of erythropoietin production by the kidney.[63] Many of these patients need regular transfusions to avoid severe symptomatic anemia. Older patients with pulmonary disease causing either chronic hypoxia or cardiac disease with chronic congestive heart failure also may require chronic transfusion to prevent symptoms.[13]

FREQUENT PAIN EPISODES

Patients with frequent severe pain episodes who have a very poor quality of life or who are unable to engage in activities of normal daily living may benefit from chronic transfusion.[13] The transfusion programs used for stroke prevention will usually prevent recurrent pain episodes.[28]

Controversial Indications for Acute or Chronic Transfusion

RECURRENT ACUTE CHEST SYNDROME

Repeated episodes of acute chest syndrome in SCD patients have been associated with worsening pulmonary function and restrictive lung disease, which may lead to severe pulmonary fibrosis, pulmonary hypertension, and cor pulmonale by adulthood.[64–68] Some authors have advocated the use of chronic transfusion protocols for the prevention and management of recurrent acute chest syndrome. Hankins and colleagues placed 27 children with SCD and history of recurrent acute chest syndrome on chronic transfusion therapy, and concluded that the number of recurrent acute chest syndrome events was mitigated, but not the severity of the events.[69] Further study is needed in this area to determine the true benefits of chronic transfusion therapy for recurrent acute chest syndrome.

PREVENTION OF PULMONARY HYPERTENSION/ COR PULMONALE

As mentioned previously, pulmonary hypertension and its resultant serious complications in both the heart and lungs have been noted to be common causes of mortality in SCD patients.[65–68,70] Gladwin and colleagues prospectively studied the prevalence and prognosis of pulmonary hypertension in 195 SCD patients, using Doppler ultrasound measurement of tricuspid regurgitant jet velocity.[70] These investigators identified significant pulmonary hypertension in 32% of these 195 patients. Based on increased severity of pulmonary hypertension, as defined by regurgitant jet velocity, 17

patients were given a variety of treatments, including RBC exchange transfusion, oxygen therapy, and vasodilator therapy (i.e., inhaled nitrous oxide). Of those 17 patients judged to be most severely affected, 11 began either chronic RBC transfusion therapy or inhaled nitrous oxide; 10 patients were alive at the time the manuscript was published.

Although Gladwin and others have introduced the concepts of Doppler ultrasound diagnosis and possible chronic RBC transfusion treatment of severe pulmonary hypertension in SCD patients, more data is required before chronic transfusion therapy can be routinely recommended for prevention of cor pulmonale and pulmonary fibrosis.

PRIAPISM

Case studies have suggested improvement in some patients with acute priapism after exchange[71,72] or simple transfusion therapy.[73,74] However, no controlled trial has been performed to establish the effectiveness of transfusion therapy in comparison with hydration, analgesia, stilbestrol,[27] or hydralazine[75,76] therapies for the treatment of acute priapism. In fact, an ***a***ssociation among ***S***CD, ***p***riapism, ***e***xchange transfusion, and subsequent ***n***eurologic events has been described in several patients and has been given the eponym *ASPEN syndrome.*[77] As a result, many centers conservatively manage priapism, using hydration and analgesia, and do not transfuse until a single episode has persisted for longer than 24 to 48 hours.[75] The indications for and the preferred method of transfusion in SCD patients with priapism require further study.

ACUTE PAIN CRISES

Episodes of severe pain, also known as *pain crises,* are the most common reason for hospital admission of SCD patients. Platt and colleagues[78] showed that occurrences of pain crises have a direct correlation with Hb levels: the more severe the anemia (i.e., the lower the Hb concentration), the less frequent the occurrence of pain crises. There is no evidence that transfusion reduces the severity or duration of pain during acute pain episodes.[13]

Therefore, simple transfusion is not indicated for the treatment of acute pain crises and could actually worsen symptoms.

NORMAL PREGNANCY

A randomized, controlled trial performed by Koshy and coworkers[59] assessed the benefits of prophylactic transfusion during pregnancy in women with SCD. Pregnant patients with SCD who were prophylactically transfused were compared with similar patients who were not transfused. No significant differences in perinatal outcome or in medical or obstetric complications were identified between these two groups. The authors concluded that prophylactic transfusion of the pregnant SCD patient, a practice common at the time their study was conducted, could be omitted without harm to mother or fetus.

Therefore, normal pregnancy is not considered an indication for prophylactic RBC transfusion.

LEG ULCERS

Statistical analysis of various methods for the treatment of leg ulcers in SCD patients (including transfusion) did not detect any differences in rate of ulcer healing.[79]

Therefore, the routine use of transfusion for the treatment of leg ulcers in SCD patients is not justified, given the long- and short-term complications of transfusion therapy.

Adverse Effects of Transfusion Therapy and Strategies for Their Prevention and Management

Although transfusion is beneficial and often necessary for treatment of SCD, adverse effects resulting from transfusion of allogeneic donor blood can lead to serious long- and short-term complications in SCD patients (Table 38–5). Both immune- and nonimmune-related complications may occur. These adverse effects, as well as recommended strategies for their prevention and management, are discussed here.

Table 38–5 **Common Immune and Nonimmune Adverse Effects of Transfusion Therapy in Patients with Sickle Cell Disease and Strategies for Their Prevention and Management**

Adverse Effect	Management Strategy
Immune-Related	
Febrile nonhemolytic transfusion reactions	*Prevention*: Transfuse leukoreduced blood products. *Treatment*: Administer antipyretic medication.
Alloimmunization to RBC antigens and delayed hemolytic transfusion reactions	*Prevention*: Transfuse RBC units matched for antigens most commonly associated with alloimmunization. *Treatment*: Transfuse RBC units matched for antigens to which antibodies have been made; provide supportive therapy for delayed reactions.
Autoimmunization to RBC antigens	*Prevention*: None known. *Treatment*: Administer corticosteroids with or without intravenous immune globulin.
Alloimmunization to platelet- or HLA-specific antigens	*Prevention*: Transfuse leukoreduced blood products. *Treatment*: Transfuse crossmatched or HLA-matched platelet products, if proven indication.
Nonimmune-Related Iron overload	*Prevention*: Provide chronic erythrocytapheresis. *Treatment*: Administer deferoxamine or deferasirox.
Transfusion-transmitted infection	*Prevention*: Use the most advanced screening tests for donated blood products; do not transfuse unnecessarily.

Immune-Related Adverse Effects

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

White blood cells (WBCs) synthesize and release various cytokines during storage of cellular blood products that may cause fever and chills (febrile nonhemolytic transfusion reactions) in the transfusion recipient.[80] Current technologies in leukoreduction filtration reduce the leukocyte count in RBCs to less than 5×10^6 WBC/unit, mitigating the development of febrile nonhemolytic transfusion reactions in recipients of leukoreduced blood products.[80] Because SCD patients typically receive large numbers of transfusions and febrile nonhemolytic transfusion reactions occur in association with 0.5% to 1% of transfusions,[81] most experts recommend the use of leukoreduced blood products for all SCD patients. In addition, an acute infection or a pain crisis can manifest with the same symptoms (i.e., fever, chills, malaise) as a febrile nonhemolytic transfusion reaction, confounding the clinical picture and possibly delaying appropriate treatment of underlying disorders in SCD patients.

ALLOIMMUNIZATION TO RBC ANTIGENS AND DELAYED HEMOLYTIC TRANSFUSION REACTIONS

Alloimmunization to RBC antigens is a common problem in transfused SCD patients, leading both to difficulty in obtaining compatible RBC units and to the development of delayed hemolytic transfusion reactions.[82–86] Delayed hemolytic transfusion reactions are especially problematic in SCD patients, in that the symptoms of a delayed hemolytic transfusion reaction can mimic those of a pain crisis and can even lead to a pain crisis,[85] complicating both the clinical diagnosis and the subsequent appropriate treatment of these patients.

The most comprehensive study of the frequency of and risk factors associated with alloimmunization in SCD patients was performed by Vichinsky and colleagues.[87] They prospectively determined the transfusion history, RBC antigen phenotype, and alloantibody development of 107 transfused African American patients with SCD. These results were compared with those from similar studies in 51 nontransfused African American SCD patients and in 19 Caucasian patients who had undergone multiple transfusions for other forms of chronic anemia. The results showed that the average alloimmunization rate for transfused SCD patients was 30%, compared with only 5% for the multiply transfused patients with other forms of anemia ($p < 0.001$). None of the nontransfused SCD patients developed alloantibodies, and the alloimmunization rate in individual SCD patients increased exponentially with increasing numbers of transfusions. Of the 32 patients who developed alloantibodies, 17 developed multiple antibodies, and 12 of these 17 patients had more than three different alloantibodies.

After conducting an RBC phenotyping study of local blood bank donors and comparing these phenotypes with those of SCD patients and of white patients with other forms of chronic anemia, the authors suggested that the increased alloimmunization rate in SCD patients most likely resulted from RBC antigenic differences between the SCD patients (African Americans) and the blood donors (the majority of whom were Caucasian). Such antigenic differences did not exist between blood donors and the multiply transfused Caucasian patients who had other forms of chronic anemia.

Because of this documented lack of phenotypic compatibility in antigen profile between the majority of volunteer allogeneic donor RBCs and those of SCD patients, many centers have suggested that SCD patients receive RBC units matched for antigens most commonly associated with alloimmunization (Table 38–6).[83,85,87]

In Vichinsky's study, comparable to reports by other researchers,[83,86–89] 66% of all alloantibodies that formed in transfused SCD patients were directed against C, E, and K RBC antigens.[87] See Table 38–6 for a summary of the most common antigens to which antibodies are made by SCD patients.

Tahhan and coworkers[90] reported that none (0%) of 40 patients studied who received matched transfusions for C, E, K, Fy^a, JK^b, and S antigens developed alloantibodies, whereas 16 (34.8%) of 46 patients who received both matched and nonmatched transfusions became alloimmunized against one or more of these antigens.

A College of American Pathologists (CAP) study, published in 2005, surveyed 1182 laboratories to determine the extent of RBC antigen phenotyping and RBC antigen matching used in the care of nonalloimmunized SCD patients throughout North America.[91] Of the laboratories surveyed by the CAP, 63% did not routinely phenotype SCD patients any differently than other patients (ABO and RhD antigen phenotyping only). The remaining one third of the North American laboratories reported routinely performing additional RBC phenotyping for SCD patients; 75% of these centers gave units phenotypically matched for additional RBC antigens C, E, and K to SCD patients.

Protocols for phenotyping and limited RBC antigen matching differ among sickle cell centers. In many academic centers, all SCD patients undergo extensive RBC antigen phenotyping before their first transfusion, a policy supported by most experts.[86,89–91] Those SCD patients who have not yet made RBC alloantibodies routinely receive RBC units phenotypically matched for the antigens responsible for most of the alloantibodies made by SCD patients to allogeneic donor RBCs, most often C, E, and K antigens.

Once an SCD patient has made an RBC alloantibody, he or she then typically receives RBC units matched for other RBC antigens to which SCD patients are known to most frequently make antibodies. C, E, K, Fy^a, Jk^b, and S are the six most common and most clinically significant antibodies made by SCD patients (see Table 38–6).[87] These concepts are supported by most centers who do extended phenotype

Table 38–6 Average Frequencies of the Most Common Red Blood Cell Alloantibodies Made by Patients with Sickle Cell Disease

Data from references 74–77.

antigen matching, and antigen-matched transfusion results in an alloimmunization rate of approximately 1% to 5%, a significant decrease compared with the rates observed among SCD patients transfused with RBCs not matched for these common RBC antigens.[9,83,86,87,90,92]

Limited donor pool programs offer a similar approach to preventing, or at least limiting, alloimmunization in SCD patients. This strategy combats RBC alloimmunization by transfusing RBCs only from donors who are ethnically or antigenically closely matched with the SCD patient, most often for the four RBC antigens (C, D, E, and K) to which antibodies are most commonly made. Sosler and colleagues suggested a model to reduce alloimmunization in SCD patients by using RBC units only from ethnically similar (African American) donors, based on the fact that 93% of African Americans shared the typical SCD phenotype of E, C, Fy^a, Jk^b, and K antigen-negativity, whereas only 7% of the Caucasion population had the same phenotype.[93] Ambruso and associates[92] reported that such a limited donor antigen-matching program can diminish by tenfold the incidence of alloimmunization in transfused SCD patients. However, administrative problems reported in Ambruso's study included difficulties in recruiting eligible donors from the African American community, in inventory management, and in distribution and transfusion of the matched blood, as well as increased expense of the program. Tahhan and coworkers[90] reported that the cost of operating an antigen-matching (not a limited donor) program was 1.5 to 1.8 times that of a standard transfusion protocol.

Hillyer and colleagues[94] conducted a retrospective review of the records of 85 patients who were enrolled in a limited donor pool antigen-matching program (Partners for Life, PFL) between January 1993 and August 2000 and reported that the average number of donors per PFL patient was 9.5, average number of RBC units transfused before PFL was 17.8, and the average number of RBC units transfused during participation in PFL was 39.4.

The overall alloimmunization rate for PFL patients was 7% (6 of 85 developed new RBC antibodies while enrolled in PFL). Of the 6 patients who developed new antibodies, 3 had previously identified antibodies at enrollment, and 3 had no previously identified antibodies. One patient with previously identified antibodies developed anti-V, another developed anti-Go^a, and the third developed anti-Cw and anti-Kp^a (all antigens not routinely matched for in PFL). Two of the three patients without previously formed antibodies developed anti-Fy^a (an antigen not matched for in PFL patients without previously formed alloantibodies). The other patient without previously formed antibodies developed an anti-E after being for in PFL 1.5 years with no antibody formation; however, she was known to have received nonantigen-matched RBCs at a nonparticipating institution immediately prior to her anti-E formation.

Although this limited donor pool program was successful in mitigating RBC alloimmunization (7% overall rate) for this group of patients, it was not successful in limiting the exposure of SCD patients to only this small, dedicated blood donor pool of 9 to 10 donors, due to technical difficulties in having these units available at the time they were needed by the patients. Only 6% of PFL patients received all of their RBC units from their dedicated donors. The majority (57%) received a combination of RBC units from their dedicated donors and antigen-matched RBC units from the general volunteer donor pool. The 7% alloimmunization rate for patients enrolled in the antigen-matching, dedicated donor PFL program is significantly lower than the published 30% rate observed in SCD patients who routinely received non-antigen-matched RBCs, but it is similar to rates observed in other antigen-matching programs without the dedicated donor aspect.[86,90,92,95]

Based on Hillyer's review and the fact that the program was expensive and labor intensive (with respect to recruitment, collection, inventory management, and distribution of dedicated RBC units), this limited donor pool program was changed to an antigen-matching program only, using primarily African American donors from the general volunteer donor pool. This program works well; nearly 13% of blood donors in the associated blood center self-identify as African American. In other parts of the country in which the general donor pool does not have such a high percentage of African American donors, special recruitment efforts within the African American community would need to be made to procure the required number of phenotypically similar RBC units for SCD patients.

The standard-setting association for transfusion medicine, the AABB (formerly the American Association of Blood Banks; www.aabb.org) is developing recommended guidelines for limited phenotypic matching RBC transfusion protocols for SCD patients. These guidelines are sensitive to the different approaches to limited antigen-matching protocols for SCD patients used by different centers. The recommendations will review the current literature regarding limited RBC antigen matching and its merits, suggest possible strategies for antigen-matching programs, and assist in engaging the community of physicians, nurses, transfusion medicine experts, blood banks, and blood centers in developing programs to suit the needs of their individual hospitals and patients.

AUTOIMMUNIZATION TO RBC ANTIGENS

Development of autoantibodies to RBC antigens in association with transfusions in certain SCD patients has been described.[96] In 1999, Castellino and associates[97] reported on the frequency, characteristics, and significance of erythrocyte autoantibodies in a large group of multiply transfused children with SCD.[97] The rate of warm (immunoglobulin G) RBC autoantibody formation in this group was 7.6%; 29% of patients with erythrocyte autoantibodies had clinically significant hemolysis thought to be caused by the autoantibody. All patients with clinically significant hemolysis had both immunoglobulin G and complement detected on the surface of their RBCs. There was a strong association between autoantibody formation and the presence of RBC alloantibodies: 86% of patients with autoantibodies also had one or more alloantibodies.

The phenomenon of RBC autoantibody formation in association with blood transfusion is not well understood, but several theories exist. Alloantibodies may bind to transfused cells and cause conformational changes in the RBC antigenic epitopes, leading to stimulation of autoantibody formation.[97] Alternatively, some SCD patients may simply have a predisposition to develop RBC autoantibodies, perhaps because of an overall dysfunction of their immune systems.[97,98] For example, the loss of a functional spleen in patients with SCD could lead to immune dysregulation, because some experimental evidence suggests that the spleen is important in the regulation of RBC autoantibody formation.[97,99]

Whatever the cause, physicians should be aware that a syndrome of clinically significant post-transfusion hemolysis may occur in SCD patients in which both autologous and transfused RBCs are destroyed (bystander hemolysis) and that hemolysis may be exacerbated by further transfusions.[100] Serologic findings may be negative or simply not helpful in identification of the autoantibody.[97] In most cases, corticosteroids with or without intravenous immunoglobulin are beneficial in slowing hemolysis and allowing for successful continuation of necessary transfusions.[100]

ALLOIMMUNIZATION TO HLA-SPECIFIC OR PLATELET-SPECIFIC ANTIGENS

As bone marrow/stem cell transplantation (BMT) becomes a viable option for selected patients with SCD,[101–107] alloimmunization to platelets presents more serious problems for this group. Friedman and coworkers[108] reported that 85% of SCD patients receiving 50 or more transfusions, 48% of SCD patients receiving 1 to 49 transfusions, and no nontransfused SCD patients demonstrated alloimmunization to human leukocyte antigen (HLA)-specific or platelet-specific antigens. Because platelet refractoriness is a serious complication during BMT, prevention of platelet alloimmunization appears prudent in this group of patients.

Most transfusion experts support the use of leukoreduced cellular blood products to prevent or reduce platelet alloimmunization and refractoriness in SCD patients, a practice employed for a variety of multiply transfused patient groups.[109–112]

Nonimmune-Related Adverse Effects

IRON OVERLOAD

Iron overload resulting in hemosiderosis is a serious long-term complication of chronic transfusion in SCD patients. The most informative reports regarding transfusion-associated iron overload were described in patients with thalassemia; see "Thalassemias" for a discussion of the pathophysiology of iron overload. Patients who develop iron overload may be treated with long-term chelation therapy in the form of deferoxamine; however, this therapy is expensive, and due to multiple side effects and a history of difficulty of administration of the drug, the compliance rate has been notoriously poor among patients.[113] However, with the November 2005 FDA approval of the first oral iron chelator available in the United States,[114] compliance to long-term chelation therapy may improve as a result of increased ease of use.

One potential transfusion methodology for the prevention of iron overload currently being investigated in SCD patients is chronic erythrocytapheresis. Chronic erythrocytapheresis procedures may be performed at 3- to 4-week intervals. In contrast to simple transfusions, the patient's own sickled RBCs are removed while an equal volume of normal donor RBCs is infused. The obvious potential benefit of chronic erythrocytapheresis compared with simple transfusion is the prevention of long-term iron accumulation and hemosiderosis.

Although it has not been universally implemented, chronic erythrocytapheresis appears to be clinically effective in reducing iron overload in chronically transfused SCD patients. Four investigative teams[19–22] have described their individual experiences with chronic erythrocytapheresis transfusion protocols for SCD patients. All suggested that erythrocytapheresis does limit iron accumulation in SCD patients, but three of the four groups reported that erythrocytapheresis does not obviate the need for chelation therapy in those patients with previously accumulated iron.[20–22] In general, ferritin levels decreased in patients undergoing chronic erythrocytapheresis who received concurrent chelation therapy, and they either mildly decreased or stabilized in patients who were not receiving chelation therapy. However, at-risk patients who began erythrocytapheresis without a long history of previous chronic simple transfusions maintained very low serum ferritin levels not requiring chelation therapy.[20–22]

Therefore, it appears that chronic erythrocytapheresis may be most beneficial when it is initiated early in the course of chronic transfusion therapy, before significant iron accumulation occurs. Nevertheless, chronic erythrocytapheresis does appear to stabilize or decrease serum ferritin levels in patients who have already developed significant iron overload and continue on chelation therapy.[20–22]

The primary potential problems with the chronic erythrocytapheresis transfusion protocol (compared with chronic simple transfusion protocols) are increased blood product exposure, with concomitant increased risks of alloimmunization to RBCs and platelets and of transfusion-transmitted infection, and the increased cost (i.e., increased numbers of blood products used, increased cost of phenotypically similar units, if chosen for transfusion, and the added cost of the automated procedures themselves).

The four published reports[19–22] indicated that SCD patients' blood product exposures increase in chronic erythrocytapheresis protocols, with reported increases in blood utilization rates ranging from 52% to almost 100% (i.e., one to two times more RBC units transfused than with previous simple transfusions of the same patients). However, of the combined 43 patients studied, only 1 patient developed an alloantibody[20] during the period of erythrocytapheresis treatment. Three of these centers used antigen-matched RBC units for the erythrocytapheresis procedures: Singer and associates[22] matched for C, E, and K; Hilliard and colleagues[21] for C, E, K, Fy^a, and Jk^b; and Adams and associates[20] for C, E, K, and Jk^b. When evaluating the very low alloimmunization rates that have been reported for chronic erythrocytapheresis protocols, it is important to realize that the majority of SCD patients studied received RBC units matched for at least the C, E, and K antigens.

The high cost of erythrocytapheresis is an important issue. Hilliard and colleagues[21] compared the total cost of 1 year of erythrocytapheresis ($36,085) with the total annual cost for simple transfusion ($26,058) and found an economically significant difference. They suggested that the added cost of chelation therapy ($29,480) with simple transfusion (for a total of $62,143) makes erythrocytapheresis without chelation a much less expensive alternative. However, for patients who have significant iron accumulation at the time erythrocytapheresis therapy is initiated, chelation therapy must be continued to achieve serum ferritin level reduction or stabilization.[19–21] This cost comparison provides further evidence that, if it is technically feasible, early initiation of chronic erythrocytapheresis in SCD patients before significant iron accumulation occurs may be preferable to long-term chronic simple transfusion and the resulting complications of iron overload and the need for chelation therapy.

TRANSFUSION-TRANSMITTED INFECTIONS

The risk of transmission via transfusion of most known infectious agents, particularly viruses, has become substantially

reduced in the developed world since the 1990s,[115,116] largely owing to improved screening tests for donated blood products. Because the risk of contracting the most harmful transfusion-transmitted diseases in the United States and many other developed countries is quite low (e.g., an estimated 1 in 2 to 4 million chance of contracting human immunodeficiency virus [HIV] per RBC unit transfused[116]), it is a generally accepted practice that blood products should not be withheld (if an appropriate clinical indication for transfusion exists) for the sole purpose of preventing a low-risk transfusion-transmitted disease.

In developing countries, however, the same cannot be said; in some countries in Africa, such as Zambia and Botswana, HIV may affect upward of one third of the country's population.[117] However, the risks of all adverse effects of transfusion (see Table 38–5), including transfusion-transmitted disease, should be balanced against the clinical need for transfusion on a case-by-case basis.

THALASSEMIAS

Pathogenesis and Clinical Pathology

Thalassemias are among the most prevalent genetic disorders caused by a single gene, occurring in high frequency in Southeast Asia, southern China, Indonesia, India, the Middle East, Africa, and the Mediterranean basin.[118] α-thalassemias are caused by mutations that reduce the synthesis of the α-globin chain of hemoglobin, and β-thalassemias from mutations that reduce β-globin synthesis. The complex molecular genetics of these disorders is beyond the scope of this discussion and has been reviewed elsewhere.[119–121] The only definitive cure for β-thalassemia major is BMT, which has cured more than 1000 individuals with β-thalassemia major worldwide. BMT is considered in all β-thalassemia major children with a suitable donor.

By definition, chronic transfusion is required to maintain wellness in homozygous individuals and compound heterozygotes with β-thalassemia major. Individuals with β-thalassemia intermedia have complex genetics and may have severe anemia that requires episodic transfusion. Hemoglobin H disease is caused by structural or functional loss of globin synthesis from three of the normal four α-globin genes. Individuals usually are not transfusion dependent, but they may require transfusion support for complications. Compound heterozygotes with β-thalassemia and hemoglobin E disease, which is very common in individuals from East Asia, can have clinical manifestations ranging from mild microcytic anemia to severe transfusion-dependent β-thalassemia major.[122]

Clinical manifestations of severe β-thalassemias include transfusion-dependent anemia, expansion of medullary bone and extramedullary hematopoiesis, severe iron overload, increased infections, retarded growth and development, and osteopenia.[120] Anemia results from severe ineffective erythropoiesis and hemolysis. The excess α-globin chain from unbalanced globin chain synthesis leads to arrested development and accelerated intramedullary apoptosis. Erythropoietic activity may be increased tenfold, but more than 95% of the erythropoietin produced may be ineffective. Precipitated α-globin in mature erythrocytes alters membrane proteins and causes oxidant damage, shortening RBC survival time. Progressive hypersplenism further reduces RBC survival.

A primary consequence of the ineffective erythropoiesis is increased iron absorption and progressive accumulation of iron in tissues. Anemia, increased erythropoiesis, and hypersplenism also cause marked expansion of the plasma volume and blood volume. Extramedullary hematopoiesis can cause pressure symptoms from perivertebral masses. Expanded marrow activity causes skeletal changes, including osteopenia and characteristic deformities in the skull and face.[123]

Goals of Transfusion Therapy

The goals of therapy in β-thalassemia major are to increase oxygen-carrying capacity by correcting the anemia, preventing progressive hypersplenism, suppressing erythropoiesis, and reducing increased gastrointestinal absorption of iron.[120] Transfusion therapy is begun early in life to ameliorate the symptoms and signs of anemia and to support normal growth and development. Adequate transfusion reduces progression of hypersplenism, delaying the need for splenectomy.[124] Suppression of erythropoiesis prevents skeletal changes, prevents complications of extramedullary hematopoiesis, and reduces pathologic fractures and other complications from osteopenia.[125] Suppression of ineffective erythropoiesis decreases transfusion requirements by reducing blood volume[126] and suppresses the increased intestinal absorption of iron.[127]

Indications for Transfusion

Transfusion therapy is initiated in childhood when the symptoms and signs of anemia are present, including growth retardation and failure to thrive. Transfusions are occasionally initiated in β-thalassemia intermedia and hemoglobin H disease to prevent facial and skull deformity from expansion of the medullary bone space. Progressive hypersplenism may require transfusion to postpone splenectomy in β-thalassemia intermedia. Splenectomy is indicated to prevent excessive transfusion requirements.[125]

Methods of Transfusion

Simple transfusion of leukoreduced RBCs to maintain a Hb level greater than 9.5 g/dL is the standard approach to transfusion in thalassemia.[121] The older practice of maintaining higher pretransfusion Hb levels[124–126] has been associated with excessive iron loading and generally is not advocated.[120,128,129] Splenectomy is recommended when hypersplenism increases the transfusion requirement beyond 200 to 250 mL/kg/year.[124,129]

Another approach to reducing iron loading has been the use of neocytes prepared by cell separators, cell processors, or other density means.[130–137] The use of "neocyte" transfusions was shown to allow a 15% extension in transfusion interval while maintaining the same pretransfusion Hb level.[137] The costs of this approach are increased blood use, increased donor unit exposure, and an estimated fivefold increase in the cost of transfusion.[137] This approach is not presently advocated by most thalassemia experts.

Erythrocytapheresis has also been applied to thalassemia transfusion therapy. The use of automated RBC exchange, returning patient and donor "neocytes" and removing the "gerocytes," resulted in a 30% reduction in RBC transfusion requirement and a 43% increase in transfusion interval.[138,139] Further clinical trials of this approach are warranted.

Adverse Effects of Transfusion

Iron Overload

A primary consequence of the ineffective erythropoiesis is increased iron absorption and progressive accumulation of iron in tissues. Anemia, increased erythropoiesis, and hypersplenism also cause marked expansion of the plasma volume and blood volume. Extramedullary hematopoiesis can cause pressure symptoms from perivertebral masses. Expanded marrow activity causes skeletal changes, including osteopenia and characteristic changes in the skull and face.[123]

Individuals with β-thalassemia major are transfusion-dependent from early life; indeed, chronic transfusion support has markedly improved the prognosis of patients with thalassemias. Transfused children develop iron overload from increased absorption caused by ineffective erythropoiesis and iron administered during transfusion. Cardiac, hepatic, and endocrine failure results in death in the second or third decade without effective therapy to remove excess iron.

Although no ideal approach to treatment of transfusion-related iron overload exists, until recently, the treatment of choice consisted of subcutaneous infusion of deferoxamine over 8 to 12 hours, 5 to 7 days a week. This approach appeared to control iron accumulation and prevent cardiac and liver damage, thereby improving life expectancy in patients with thalassemia. However, the difficulty of administration of deferoxamine and the many side effects caused a poor compliance rate in most patients.

On November 9, 2005, the FDA announced the approval of deferasirox, the first orally absorbed iron chelator developed to treat chronic iron overload due to multiple blood transfusions available for use in the United States.[114] Deferasirox was approved through the FDA's accelerated approval program; further clinical studies from the company who makes the drug are required to maintain the drug's approval and confirm clinical benefits. Clinical trials of less than 1 year's duration showed reduction in hepatic iron concentration following once-daily (oral) deferasirox therapy in patients who had been receiving multiple transfusions. Side effects such as nausea and abdominal pain and other less common difficulties were noted.[140] However, the greater ease of administration of this drug and its apparent efficacy with typically mild side effects may markedly improve the care and treatment of patients with transfusion-dependent iron overload.[141] In other countries, such as India, different oral iron chelators have been widely used, safely and with good success, for the treatment of transfusion-dependent iron overload in patients with thalassemia.[142]

Alloimmunization to RBC Antigens

Reported rates of alloimmunization to RBC antigens in chronically transfused thalassemia patients range from 5% to 30%.[143–147] The largest of these studies followed alloimmunization rates in 973 Greek patients, primarily children, and found an alloimmunization rate of 23% in this group.[146]

Some evidence exists that thalassemia major patients who begin chronic transfusion therapy at younger ages develop fewer alloantibodies.[145,146] Michail-Merianou and colleagues reported that children who began transfusion therapy before age 12 months had a 9% alloimmunization rate; children who started chronic transfusions after age 12 months had a 39% alloimmunization rate.[145]

There are no agreed-upon hypotheses as to what specifically affects increased alloimmunization rates in thalassemia patients. Ethnic differences have been proposed, but there is little data to support this claim.[144–148] Leukoreduction has been suggested as a possible means of decreasing alloimmunization in thalassemics, but no data exists to support this hypothesis. Splenectomy has also been suggested as a trigger for increased alloimmunization to RBCs, but Singer and colleagues found that although such a trend existed in their group of patients studied, it did not reach statistical significance.[149]

Risks of alloimmunization in thalassemic patients include delay of transfusion due to difficulties in finding compatible RBC units, if patients make multiple alloantibodies; a potential for hemolytic disease of the newborn in thalassemic patients who become pregnant; and a possible relationship between RBC alloantibody development and secondary RBC autoantibody development and/or autoimmune hemolytic anemia.[149–151]

Some studies have shown that limited phenotypic RBC antigen matching reduces the rate of alloimmunization in thalassemia patients, particularly in those patients whose first transfusion occurred after age 12 months.[145,146,149] More data is required, however, before evidence-based recommendations can be made regarding the feasibility of RBC phenotypic matching for thalassemic patients.

Chapter 39

Transfusion to Bone Marrow or Solid Organ Transplant Recipients

Richard M. Kaufman • Steven R. Sloan

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Kinetics of Engraftment and Blood Product Support

In a standard hematopoietic stem cell transplant (HSCT), the recipient's bone marrow is ablated using chemotherapy and irradiation. Between the time of stem cell infusion and engraftment/hematologic recovery, red cell and platelet transfusions are critical to sustain the recipient. Although the HSCT patient's blood component needs may be substantial, the indications for transfusion are essentially the same as for other clinical settings. However, a number of blood bank considerations specifically apply to the HSCT situation.

Three sources of hematopoietic stem cells are presently in use for clinical transplantation: bone marrow, mobilized peripheral blood stem cells, and umbilical cord blood. The cellular composition of these three products differs considerably.[1,2] Clinically, the single most important factor seems to be the dose of CD34+ cells contained in each product type. Peripheral blood stem cell products contain about three times more CD34+ cells than bone marrow–derived products, and 10 times more CD34+ cells than umbilical cord blood (Table 39–1). Peripheral blood stem cells grafts also contain 5 to 10 times more mature T cells than bone marrow. Umbilical cord blood contains far fewer CD34+ cells and T cells than either peripheral blood stem cells or bone marrow. Several randomized studies directly comparing peripheral blood stem cells to bone marrow have all shown that hematologic recovery occurs faster in recipients of peripheral blood stem cells than in recipients of bone marrow. The median number of days to a platelet count grater than 20,000/L is about 13 for peripheral blood stem cells recipients versus about 19 days for bone marrow recipients.[3–8] The more rapid engraftment of peripheral blood stem cells products has been primarily attributed to their higher CD34+ cell content. As would be expected, faster engraftment rates have been associated with decreased blood component requirements.[9,10] Umbilical cord blood grafts contain significantly fewer CD34+ cells, so recipients of these grafts predictably demonstrate slower hematologic recovery (median of 50 days to exceed 20,000/L platelets).[1]

Although peripheral blood is now by far the most commonly used source of stem cells for transplantation, interest in umbilical cord blood transplants has increased in recent years. Only about 30% of patients requiring HSCT have a human leukocyte antigen (HLA)-matched related donor, and 50% to 80% of the remaining transplant candidates will find an unrelated matched donor.[11] For patients lacking a matched donor, umbilical cord blood transplantation may represent a critical therapeutic option because HLA matching is not as important for umbilical cord blood transplants as it is for other sources of HSCT. This is especially true in cases where transplantation is needed urgently and there is insufficient time available to do a search for a matched unrelated donor. Relative to bone marrow and peripheral blood stem cells, umbilical cord blood contains higher numbers of primitive long-term culture-initiating cells and has superior engraftment in SCID mice.[12] Umbilical cord blood appears to require less stringent HLA matching than bone marrow or peripheral blood stem cell products and is associated with a lower incidence of graft-versus-host disease (GVHD). The major disadvantage of umbilical cord blood is the low number of CD34+ cells. This is a particular problem in the adult transplant setting, given the larger size of adult versus pediatric recipients. The low CD34+ cell content is associated with a higher rate of graft failure as well as slower hematologic recovery.[13–15] Despite this key limitation, umbilical cord blood transplants have been used increasingly for adult patients. One approach is to transplant two (or more) umbilical cord blood products simultaneously. Double-unit grafts appear to facilitate engraftment and hematologic recovery. One graft eventually predominates and generates 100% of the recipient's hematopoietic cells. It has been hypothesized that the nonsustained graft helps the predominating unit engraft via as-yet undefined immunologic mechanisms.[16]

In addition to CD34+ cell dose, a number of clinical factors may affect both the rate of hematologic recovery and transfusion requirements after HSCT. More rapid platelet recovery has been associated with a higher pretransplant platelet count, and with HLA-identical sibling donor transplants. Factors that have been associated with slower platelet recovery include the presence of fever, GVHD, hepatic veno-occlusive disease, previous radiation treatment, and the use of post-transplant granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor.[17] The administration of recombinant human erythropoietin (EPO) has been shown to accelerate red blood cell (RBC) recovery and decrease RBC product requirements among allogeneic HSCT patients.[18–21] Finally, the conditioning regimen used also affects hematologic recovery. In particular, recipients of nonmyeloablative HSCT (known as *reduced intensity conditioning* or

Table 39–1 Composition of Unmanipulated Allogeneic Stem Cell Products

Product	Median CD34+ Cell Dose × 10^6/kg	Median T-Cell Dose × 10^8/kg
Bone marrow	1.4	0.3
Peripheral blood	4.2	1.8
Cord blood	0.12	0.05

Data from Schmitz N, Barrett J. Optimizing engraftment—source and dose of stem cells. Semin Hematol 2002;39:3–14.

mini-transplants) typically have significantly decreased transfusion requirements relative to patients undergoing traditional myeloablative conditioning.[22,23]

ABO

Unlike blood transfusion, the ABO system is not a barrier to HSCT. Up to 40% of allogeneic HSCTs involve donor–recipient pairs that are ABO-mismatched.[24] Such mismatches are classified as major (recipient has ABO antibody against donor RBCs), minor (donor has ABO antibody against recipient RBCs), or major-minor (ABO mismatch in both directions). Examples of these mismatches and potential clinical consequences are summarized in Table 39–2. Although HLA compatibility has critical consequences for stem cell transplantation, most published studies currently indicate that ABO compatibility has no significant effect on overall rates of survival, disease recurrence, graft failure, or GVHD.[25–32]

Major ABO Mismatch: Immunohematologic Consequences

The recipient of a major ABO incompatible HSCT (e.g., group A donor → group O recipient) is at risk for several different hemolytic complications. First, red cells contaminating the graft may be immediately destroyed by preformed ABO antibody in the recipient. This risk is lower for recipients of peripheral blood stem cells, because these products contain far fewer red cells than are found in bone marrow grafts.[24] To prevent acute hemolysis, stem cell products may be depleted of RBCs. Typically, processing yields products containing less than 10 mL of incompatible RBCs, which effectively prevents most acute hemolytic reactions. Plasma exchange has been rarely used to lower the recipient's ABO antibody titer.

A second potential adverse consequence of major ABO-mismatched HSCT is delayed red cell recovery post-transplantation. This is a form of pure red-cell aplasia (PRCA) that results from recipient plasma cells continuing to produce antibody against donor ABO antigen, despite cytoreductive therapy. On histologic examination, the bone marrow is characteristically devoid of erythroid precursors, and reticulocytopenia is observed in the peripheral blood. A persistently elevated ABO antibody titer is usually seen. In some cases, patients remain red cell transfusion dependent for months to years, until the anti-ABO antibody titer drops to a low level.[33–42] Of note, although red cell *reconstitution* is delayed in these cases, red cell *engraftment* is not. Using in vitro colony assays, the presence of early erythroid progenitors can be demonstrated in the recipient's bone marrow at the same time point after transplant that myeloid progenitors are detected.[43] Early erythroid progenitors do not express ABO antigens and survive normally. On differentiation, the erythroid precursors begin expressing ABO antigens; at which point they are targeted for destruction within the bone marrow by host ABO antibodies. Proposed risk factors for the development of PRCA include high initial host antidonor antibody levels,[39] the use of cyclosporine A for GVHD prophylaxis,[34] and the use of nonmyeloablative conditioning regimens.[34,44,45] The optimal management strategy for PRCA is currently unclear. Various investigators have reported success with high-dose EPO,[46–48] plasma exchange,[24,42] immunoabsorption,[49] rituximab,[38] donor lymphocyte infusion,[50] discontinuation of cyclosporine and antithymocyte globulin.[51,52] In very rare cases, erythroid maturation gets beyond the precursor stage and mature donor-type red cells leave the bone marrow—only to be cleared by persistent recipient ABO antibodies.[53,54] This situation occurs far less often than PRCA.

Minor ABO Mismatch: Immunohematologic Consequences

Minor ABO-incompatible HSCT (e.g., group O donor→ group A recipient) can lead to immediate hemolysis from passively transfused donor ABO antibody and delayed hemolysis (known as the *passenger lymphocyte syndrome*). Minor ABO incompatibility does not appear to affect overall rates of graft rejection, GVHD, or patient survival.[26,27,55,56] Depletion of donor plasma in the graft generally eliminates the problem of immediate hemolysis caused by passively

Table 39–2 ABO-Mismatched Stem Cell Transplantation

ABO Mismatch Type	Example	Physiology	Potential Complications
Major	A donor → O recipient	Recipient has antibody against donor RBCs	*Immediate:* Hemolysis of RBCs in graft *Delayed:* Pure red cell aplasia *Delayed:* Hemolysis of RBCs produced by graft (very rare)
Minor	O donor → A recipient	Donor has antibody against recipient RBCs	*Immediate:* Hemolysis from passively transfused antibody *Delayed:* Donor lymphocyte syndrome/ hemolysis
Major-minor	A donor → B recipient	Both of the above	All of the above

transfused ABO antibody. The more serious potential problem is the passenger lymphocyte syndrome. In this syndrome, mature donor lymphocytes are transfused into the host along with the stem cell graft. The donor lymphocytes produce anti-ABO antibodies that bind to and cause hemolysis of circulating host RBCs. This complication typically occurs 1 to 3 weeks after the transplant and is heralded by a positive direct antiglobulin test (DAT) and a fall in hematocrit. Hemolysis may be massive.[57] In some cases, hemolysis becomes clinically apparent 1 to 2 days before the causative antibody is detectable in the recipient's plasma (i.e., before the DAT turns positive).[53,58] Currently, the standard practice is to transfuse either group O or donor group RBCs and to monitor the patient closely for clinical and laboratory evidence of hemolysis. Red cell exchange transfusion has been performed in this setting, but is usually unnecessary.

Blood product selection for ABO-mismatched HSCT is detailed in Table 39–3. During the period between transplant and engraftment, the blood bank should provide RBCs that are compatible with the plasma of both donor and recipient and platelets/plasma that are compatible with both donor and recipient RBCs. These transfusion restrictions are begun on day 0 of HSCT, or earlier if feasible. Because these patients are immunocompromised and therefore at risk for transfusion-associated GVHD, it is critically important to irradiate all cellular blood components.

ABO antigens are widely expressed on endothelial tissues; thus, HSCT recipients may be considered ABO chimeras even after full RBC recovery. For example, a type A recipient of a type O transplant will eventually convert to having 100% type O (donor-type) red cells—but the patient's plasma will usually lack the anti-A normally seen in a type O individual.

Non-ABO Antibodies

In principle, donor lymphocytes may make an antibody in response to any recipient red cell antigen; conversely, recipient lymphocytes may make an antibody against any donor red cell antigen. In practice, however, clinically significant hemolysis caused by non-ABO RBC antibodies (e.g., Rh system antibodies) occurs only rarely in the post-HSCT setting.[59–61] Ting and colleagues[62] observed the formation of non-ABO antibodies in 13 of 150 patients (8.7%) after bone marrow transplantation. de la Rubia[63] reported a 3.7% rate of non-ABO antibody formation in 217 stem transplant recipients. The rate of clinically significant hemolysis seems to be lower still: in a review of 427 stem cell transplants, Young and colleagues[60] found an approximately 1% incidence of alloimmune hemolysis caused by non-ABO antibodies. When such hemolysis does occur though, it may be severe.[64] Red cell antigen systems that have been implicated in post-transplantation hemolysis include Rh, Kell, Kidd, MNS, and Lewis.[59] Because clinically significant hemolysis caused by non-ABO antibodies is seen so rarely, it is not considered necessary to give antigen-negative red cell units unless the patient forms the corresponding antibody.

Prophylactic Platelet Transfusions

A period of thrombocytopenia is expected between the time of myeloablation and stem cell engraftment. In this setting, the vast majority of platelet transfusions given are administered to nonbleeding patients as prophylaxis, rather than to treat active bleeding. For many years, a platelet count of 20,000/μL was used as a standard transfusion trigger.[65,66] Later, it was demonstrated that prophylactic platelet transfusions can safely be provided using lower thresholds, with considerable savings in both product inventory and cost. In an observational study of leukemia patients, Gmur and colleagues[67] reported that a platelet transfusion trigger of 5,000/μL could safely be used for patients without fever or bleeding (a 10,000/μL trigger was used for patients with such comorbidities). Later, two randomized, controlled trials of patients with acute leukemia directly compared the use of a 10,000/μL versus 20,000/μL trigger.[68,69] Both of these studies, as well as a third nonrandomized prospective study,[70] showed no increased bleeding risk when a 10,000/μL trigger was used. Of note, all of these trials included provisions for transfusing patients at higher platelet counts if specified risk factors for bleeding (e.g., fever) were present. Few studies have directly examined platelet transfusion triggers in the specific setting of HSCT. Nevertheless, the 10,000/μL trigger has been widely applied to the HSCT patient population, and it appears to be safe for patients lacking associated clinical

Table 39–3 **Product Selection for ABO-Mismatched HSCT: Peritransplant Period**

Recipient	Donor	RBC	PLT 1st Choice	PLT Next Choice*	FFP
A	B	O	AB	A, B, O	AB

factors (e.g., infection, GVHD).[71,72] Often, these clinical factors are more important determinants of bleeding risk than the platelet count alone. Approximately two thirds of bleeding events after HSCT occur in patients with platelet counts above 20,000/μL.[17,73]

Alloimmunization and Platelet Refractoriness

Platelet refractoriness may be defined as an inappropriately low platelet increment following repeated platelet transfusions. Several nonimmune factors can cause platelet refractoriness, including fever, sepsis, disseminated intravascular coagulation, medications, bleeding, splenomegaly, hepatic veno-occlusive disease, and GVHD. In a subset of cases, platelet refractoriness is caused by alloimmunization. Platelets express HLA class I antigens, ABO antigens,[74] and several platelet-specific antigens. Any of these molecules could potentially serve as an immune stimulus in a transfusion recipient. Antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness. Notably, less than half of all platelet-refractory patients have demonstrable antiplatelet or anti-HLA antibodies.[75,76] Platelet counts obtained at 10 minutes and 1 hour post-transfusion that repeatedly fail to demonstrate an adequate corrected count increment usually indicate an immune mechanism of platelet destruction.[77] If the 10 minute and 1 hour post-transfusion platelet count shows a reasonable increment but the platelet count falls back to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed. HLA antibody screening (*percent reactive antibody,* or PRA) provides valuable supporting evidence that allosensitization has occurred.[78,79] A patient with a PRA greater than 70% may be considered to be *severely immunized*[80] and a good candidate for HLA-matched platelets.

Although they express HLA class I antigens, platelets themselves are fairly weak immunogens. It has been shown that contaminating leukocytes in platelet products are primarily responsible for stimulating HLA antibody formation in platelet transfusion recipients.[81–84] Thus, removal of white cells from blood products helps prevent alloimmunization and platelet refractoriness. The definitive study showing this was the Trial to Reduce Alloimmunization to Platelets (TRAP study),[84] which compared alloimmunization rates in 530 newly diagnosed acute myelogenous leukemia patients randomized to receive either unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PC); filtered single-donor apheresis platelets (F-AP); or UVB-irradiated pooled platelet concentrates (UVB-PC). Anti-HLA antibodies were detected in 45% of controls, compared with 17% to 21% of patients receiving modified platelets. Of the control group patients, 13% became platelet-refractory, versus only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Once platelet refractoriness has been demonstrated, several strategies may help in obtaining therapeutic platelet increments in vivo. A trial of ABO-matched, fresh (1 to 2 days old) platelets may be helpful.[85] In cases of immune-mediated refractoriness, a trial of HLA-matched platelets,[78,86–88] antigen-negative platelets,[89] or crossmatched platelets[90–92] should be considered. Due to the high degree of polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and HLA-B locus matches, leading to the use of platelets mismatched at one or more loci. Grade A (HLA identical) or BU (partially homozygous) matched platelets provide the highest probability of a successful response.[87]

SOLID-ORGAN TRANSPLANTATION

The total number of organ transplants performed in the United States has been gradually increasing over the past several years. Indeed, between 2000 and 2004, the total number of transplants performed in the United States increased by 16%, to 27,036 per year. During this time period, the numbers of kidney and liver transplants increased while the number of heart transplants remained stable (United Network of Organ Sharing, www.unos.org). The blood transfusion requirements for a transplant depend on several factors, including the type of organ being transplanted, the clinical condition of the patient, the experience of the transplant center, and use of antifibrinolytic agents such as aprotinin.

Blood Product Support

Liver Transplants

Although liver transplants often require substantial transfusion of blood components, the transfusion needs of these patients has declined as centers have gained experience.[93] The transfusion requirements can vary significantly and depend on the medical center and on the complexity of the case and the patient's condition.[94,95] Red cells are transfused in 80% to 90% of cases, and the median number of RBC units required ranges from 4 to 12, depending on the center.[93,96–98]

Although not all patients undergoing liver transplantation require platelet transfusions, some patients with liver failure develop thrombocytopenia that can be compounded by blood loss during surgery. Platelets are transfused in about 55% of cases,[93] and the median number of platelets transfused is about 10 whole blood–derived platelet units.[93,96–98]

Plasma transfusions are also used to support about 75% of liver transplants.[93] Patients with more severe coagulopathies and greater blood loss during surgery are more likely to require plasma transfusions.[94,95] The use of plasma transfusions varies greatly between institutions,[93] with the median number of units of plasma used ranging from 0 to 19.[93,96–98] Additionally, some institutions use cryoprecipitate for some of their liver transplants.[97,98]

Heart Transplants

Although heart transplant patients do not usually have a coagulopathy or thrombocytopenia prior to surgery, they invariably require blood component support because of the blood volume diverted to the cardiopulmonary bypass circuit and because platelets are damaged when flowing through bypass circuits. There is significant variability in product usage between institutions, with these patients using a median of 3 to 9 units of red cells, 3 to 10 units of plasma, and 0 to 13 units of platelets.[96,99,100]

Lung Transplants and Heart-Lung Transplants

Transfusion support for single or double lung transplants differs significantly, because double lung transplants require cardiopulmonary bypass. Single lung transplants have been reported to require a mean of 1.7 units of red cells, 1.5 units of platelets, 1.3 units of plasma, and 0.8 units of cryoprecipitate[101]; double lung transplants or heart-lung transplants require 6.4

to 13.3 units of red cells, 3 to 13.6 units of platelets, 4 to 8 units of plasma, and 0 to 15.8 units of cryoprecipitate.[100–102] One report found that the use of aprotinin was able to reduce the use of red cell and whole blood units from a mean of 13.3 to 7, the use of plasma units from a mean of 6.1 to 2, and to eliminate the use of platelets or cryoprecipitate.[102]

Other Solid Organ Transplants

Small bowel transplants are relatively uncommon. They can require a median of 7 units of red cells, 3 units of plasma, and 8 units of platelets.[96] The far more common kidney transplants usually only require 0 to 2 units of red cells.[96]

ABO

Overview

Endothelial cells express ABO antigens.[103,104] Hence, the potential exists for antibody-mediated rejection when a transplanted vascular organ expresses ABO antigens that are absent in the patient (i.e., there is a major ABO mismatch). However, because the supply of organs is severely limited and organs are sometimes needed emergently or are provided by living related donors, a variety of centers have attempted to perform ABO mismatched organ transplants using a variety of strategies. Overall, success has been mixed. Currently, although 70% to 80% of ABO-compatible hearts, livers, or cadaveric kidneys survive 1 year, only 50% to 60% of ABO-incompatible transplants survive at least 1 year, even though those patients often undergo intensive immunosuppression.[105]

Results from many reports of transplanting ABO-mismatched organs need to be viewed with caution because of the paucity of controlled studies. Even without special protocols, the results of ABO-incompatible organ transplants are variable; whereas some transplanted organs are rapidly rejected, others survive for long periods of time. Also, in addition to ABO issues, transplant results are affected by the medical status of patients prior to transplant and by the immunosuppressive treatments used to prevent or treat rejection.

One strategy to breach the ABO barrier is to limit the transplants to those in whom only low levels of the ABO antigen are expressed. Specifically, some transplanters have limited ABO-incompatible transplants to those in which the donor types as an A_2 and the recipient lacks the A antigen entirely.[106,107]

Another strategy for performing ABO-incompatible transplants is to limit the transplants to patients whose immune system is less likely to reject the ABO-incompatible organ. One way to identify such patients may be to limit ABO-incompatible transplants to patients with low titers of the relevant isohemagglutinin. Another set of patients that may not reject ABO-incompatible organs is very young children with immature immune systems. Isohemagluttinins are usually absent in the first few months of life and the titers usually remain low in the first year of life.[108]

A third strategy for performing ABO-incompatible solid organ transplants is to suppress the immune system with some combination of drugs, plasmapheresis, and splenectomy.

ABO Compatibility in Liver Transplants

In comparison to other vascular organs, the liver is thought to be less susceptible to humoral rejection, possibly because the Kupffer cells may be able to remove antigen–antibody complexes.[109] Indeed, HLA matching is not usually performed for liver allografts.[110,111] Early studies suggested that ABO barriers could be ignored because patients rarely developed hyperacute rejection.[112] However, additional experience revealed that ABO-incompatible liver allografts can undergo ABO-mediated hyperacute rejection[113,114] and the allografts have a significantly diminished survival. For instance, one group reported a 30% 2-year graft survival rate for ABO-incompatible livers compared with a 76% to 80% 2-year graft survival rate for ABO-compatible liver allografts.[115] Other centers have also found a significant decrease in 1-year or 2-year survival of ABO-incompatible liver allografts.[105,116]

ABO-incompatible liver transplants appear to be safer in young children. In patients less than 1 year old, the 5-year survival following an ABO-incompatible liver transplant was 76% at one Japanese center.[117] Similar results have been seen in an American hospital with 81% of ABO-incompatible allografts surviving long-term following transplants into children who were less than 3 years old.[118]

One report suggests that group A_2 livers can be safely transplanted into blood group O patients.[119] However, further work is needed in this area because this report only included 6 patients who suffered nine episodes of rejection that responded to standard treatment.

Plasmapheresis has been used by some groups to remove incompatible isohemagglutinins either before or after transplant.[105,120,121] However, there is no evidence that plasmapheresis improves survival of the graft or the patient since the patients generally received intensive immunosuppressive treatments and graft survival rates were usually no better than 60%. Additionally, plasmapheresis may be associated with increased septic complications in these patients.[122]

ABO Compatibility in Heart and Lung Transplants

ABO compatibility is a requirement for heart transplants in adults. Five of eight cases of unintentional transplants of ABO-incompatible hearts resulted in hyperacute rejection.[123] An unintentional transplant of an ABO-incompatible heart and lung also resulted in hyperacute rejection,[124] whereas an unintentional ABO-incompatible lung transplant was able to be sustained for at least 3 years through the addition of antigen-specific immunoadsorption, anti-CD20 monoclonal antibody, and recombinant soluble complement receptor type 1 to an immunosuppressive regimen of cyclophosphamide, antithymocyte globulin, cyclosporine, mycophenolate mofetil, and prednisone.[125]

Increasing evidence demonstrates that infants can be transplanted successfully with ABO-incompatible hearts. This finding was originally reported in 2001 by West and colleagues[126]; experience in almost 50 patients at several medical centers has shown that many young infants can be safely transplanted with ABO-incompatible hearts.[127]

Although most ABO-incompatible heart transplants have been performed in infants too young to produce isohemagglutinins, the blood banks supporting such transplants have implemented special procedures. Starting prior to a possible ABO-incompatible transplant, patients are usually provided with blood components lacking isohemagglutinins (i.e., AB plasma and washed cellular blood components). Even with these precautions, a patient's plasma may contain incompatible isohemagglutinins that were passively transfused, of maternal origin, or were produced by the infant's own

immune system. Such isohemagglutinins are usually removed immediately prior to the transplant either by plasmapheresis or by whole blood exchange as the patient is placed on cardiopulmonary bypass for surgery. Incompatible anti-A and/or anti-B antibodies that are detected after the transplant may be removed by plasmapheresis.

Although the mean age of patients that have been successfully transplanted with incompatible hearts is 117 days,[127] patients as old as 14 months have received transplants.[128] However, experience with patients older than age 8 months is limited; one patient who received a transplant at age 9 months developed rejection mediated by an isohemagglutinin that was successfully treated with rituximab.[128]

ABO Compatibility in Renal Transplants

Early experiences demonstrated that transplantation of an ABO-incompatible kidney could lead to hyperacute or acute rejection; the 1-year survival of such transplanted kidneys was only 4%.[129–133] However, many attempts have been made to transplant ABO-incompatible kidneys because the wait list for cadaveric kidneys is very long and many patients are offered ABO-incompatible kidneys from family members. This has been of particular importance in Japan where traditionally very few cadaveric kidneys have been made available for transplant.

Many reports suggest that the safest ABO-incompatible renal transplants are ones in which the kidney is from a donor whose cells express the A_2 antigen and the recipient is of blood group O or B with low titers of anti-A antibodies. An early report of A_2-incompatible transplants using the standard immunosuppression of the time found limited success with 12 of 20 such grafts surviving long-term and 8 of the grafts being lost within 1 month.[134] Subsequent work suggested that patients with an immunoglobulin M titer of <64 against A_2 red blood cells were less likely to reject an A_2 kidney than patients with higher anti-A_2 titers.[135] Some American transplant programs currently transplant kidneys in which the A_2 antigen confers major incompatibility. These programs have restricted the transplants to patients whose initial anti-A antibody titer is ≤4 or ≤8, which in some cases had been reduced by pretransplant plasmapheresis.[135–139] Even with these protocols occasional cases of acute rejection have occurred. However, these centers have reported at least 90% 1-year and 85% 5-year survival of the grafts, which is similar to graft survival rates that these centers have achieved with ABO-compatible transplants.[138,139]

Starting in the 1980s, some centers tried transplanting kidneys with major ABO incompatibility with the recipients, based on expression of A_1 and/or B antigens on the renal allografts. Several of these centers modeled their immunosuppressive treatment protocols on the approach used by a Belgian group that included pretransplant antibody removal by plasmapheresis or immunoadsorption, steroids, azathioprine, cyclosporine or tacrolimus, antilymphocyte globulin, and splenectomy.[140] In some of these series patients also received pretransplant infusion of the relevant A and/or B substance.[141] In most cases in which the transplanted kidneys survived, incompatible isohemagglutinins returned to the patient's plasma and the kidney continued to express the ABO antigen.[141–143]

At least 309 ABO-incompatible renal transplants have been reported with a combined 1-year graft survival rate of 83%,[130] which is equivalent to the survival rate seen with ABO compatible grafts in the multicenter Collaborative Transplant Study.[105] However, data from these selected reports must be considered cautiously; long-term analysis of the original patients reveals that 23 of 31 ABO-incompatible renal transplants from living related donors have survived at least 15 years, which is a long-term survival rate equivalent to that seen with ABO-compatible renal transplants at that center.[141] The specific immunosuppressive treatment is especially important in ABO-incompatible transplants, with one report finding that the addition of mycophenolate mofetil allowed ABO-incompatible kidneys to survive as long as ABO-compatible transplants.[144]

Several centers have continued to perform transplants using this or similar approaches. In some of these protocols, patients only receive transplants if plasmapheresis can reduce the anti-A/B antibody titer to no more that 4:1 or 8:1 before the transplant. Recent studies demonstrate that pretransplant removal of anti-A/B antibodies is necessary for successful transplants of ABO-incompatible kidneys (other than A_2 kidneys).[145,146] Some studies also suggest that splenectomy is unnecessary for ABO-incompatible renal transplants, especially if patients are treated with newer potent immunosuppressive treatments that can modify B-cell responses, such as rituximab, mycophenolate mofetil, or intravenous immunoglobulin (IVIG).[141,145,147–151]

Non-ABO Antibodies

Although transplanted organs can induce alloantibodies to erythrocyte antigens,[152] such antibodies have little impact on graft survival. Early studies suggested that renal allografts survived longer if the Lewis type of the kidney donor matched the type of the patient.[153] However, this has not been seen in more recent studies. It is now accepted that kidneys can be safely transplanted into patients with preexisting anti–red cell antibodies such as anti-RhD.[154–156]

Pretransplant Transfusion for Kidneys to Increase Survival

Starting in 1973, studies have shown that blood transfusions prior to renal transplantation prolong survival and reduce rejection of renal allografts.[96,157] The beneficial effect of pretransplant transfusion had only been seen for kidney transplants. Then, new immunosuppressive drugs such as cyclosporine were developed and it was unclear whether transfusions conferred any additional benefit to patients who were receiving these drugs.[96,158] Because it had also become clear that transfusions can transmit infectious diseases and induce alloimmunization, the practice of pretransplant transfusion to prolong the survival of renal allografts was largely abandoned.

Several recent studies have found that even with the use of immunosuppressive drugs such as cyclosporine or tacrolimus, pretransplant transfusion may still decrease the risk of rejection of the renal allograft.[159–162] In the pediatric setting, this benefit was observed in patients receiving one to five transfusions, but was not seen in patients receiving more than five transfusions.[161] Despite these studies, most centers are not currently using transfusions for this purpose.

Passenger Lymphocyte Syndrome

Donor B lymphocytes contained in solid organ allografts can sometimes produce anti-erythrocyte antibodies, resulting in a condition known as the *passenger lymphocyte syndrome.*

Typically, the antibodies are detected 1 to 2 weeks after the transplant as a positive DAT.[96] Elution reveals anti-A and/or anti-B. These patients may develop hemolysis, which can be severe in rare cases. Although at least one death has been attributed to this hemolysis, most patients recover and the antibody usually disappears in about 1 month.[96,163]

Most cases of passenger lymphocyte syndrome involve antibodies to ABO antigens. As reported by Ramsey's extensive analysis of the literature,[163] the observed rate of ABO antibodies and hemolysis from passenger lymphocyte syndrome is lowest in kidney transplant patients (17% and 9%, respectively), intermediate in liver transplant patients (40% and 29%, respectively), and highest in heart-lung transplant patients (both 70%). Notably, most of these reports were prior to the advent of cyclosporine or tacrolimus. In kidney transplant patients, cyclosporine increases the incidence of passenger lymphocyte syndrome so that 30% of patients develop antibodies and 17% develop hemolysis.

No risk factors for passenger lymphocyte syndrome have been proven. It has been hypothesized that passenger lymphocyte syndrome is more likely when the donor has a high-titer antibody or when the recipient is a nonsecretor or is of the A_2 subtype.[163,164] Although it is possible that these donor and recipient characteristics are risk factors for passenger lymphocyte syndrome, no large studies have been performed, and individual case reports demonstrate that secretors and non-A_2 patients can develop passenger lymphocyte syndrome. The only prophylactic treatment that has been shown to reduce the incidence of passenger lymphocyte syndrome in renal transplant patients is post-transplant irradiation of the graft.[163,165]

Passenger lymphocyte syndrome resulting in hemolysis has rarely been caused by non-ABO antibodies including anti-RhD, anti-Rh^e, anti-Rh^c, anti-Rh^E and anti-Jk^a antibodies[163,166–168] Case reports suggest that passenger lymphocyte syndrome involving these antibodies only occurs when the donor is alloimmunized to the antigen prior to donating the organ.

Plasmapheresis to Prevent or Treat Anti-HLA Antibody-Mediated Rejection of Transplanted Organs

No randomized, controlled prospective trials have analyzed the efficacy of plasmapheresis in preventing or treating anti-HLA antibody-mediated rejection of transplanted solid organs. However, several transplant centers incorporate plasmapheresis into their treatment protocols based on success from case reports, case series, and retrospective analyses of local data. Plasmapheresis in this setting has been used for cardiac and renal transplants, and very rarely with hepatic transplants.

Patients who have significant levels of anti-HLA antibodies at the time of cardiac transplant have reduced long-term survival,[169] and patients with antibodies that react against the heart donor's HLA antigens appear to have a very high mortality rate.[170] If patients with anti-HLA antibodies are treated by plasmapheresis followed by IVIG immediately before transplant, patient and cardiac allograft survival rates improve to levels comparable to those of patients without pre-existing anti-HLA antibodies.[171,172] Alternatively, some institutions have had success performing multiple plasma exchanges on alloimmunized patients awaiting heart transplants.

Several centers have also reported success with treating acute humoral rejection of cardiac allografts with an immunosuppressive regimen that includes plasmapheresis.[173–179] In some cases in which the rejection failed to respond to multiple pharmacologic interventions, there was significant clinical improvement following plasmapheresis.[175]

Plasmapheresis has also been used to remove anti-HLA antibodies prior to renal transplants. This approach has been used with apparent success in renal transplant patients receiving either living donor allografts[180,181] or cadaveric allografts.[182] Plasmapheresis combined with other immunosuppressive therapy such as IVIG has also been used to successfully treat acute humoral rejection of renal allografts.[178,179,183,184]

Plasmapheresis for primary allograft nonfunction after liver transplantation has been attempted with mixed results.[185,186]

TRANSFUSION-RELATED COMPLICATIONS IN IMMUNOCOMPROMISED PATIENTS

Cytomegalovirus Infection

Cytomegalovirus (CMV) is a member of the herpesvirus group, which includes the herpes simplex viruses 1 and 2, Epstein-Barr virus, and varicella-zoster virus. CMV is capable of infecting a variety of cell types, including mature white blood cells and their progenitors. In the immunocompromised host, CMV infection can lead to significant morbidity and mortality. Allogeneic HSCT patients in particular are at risk to develop serious manifestations of CMV disease, which include pneumonitis, gastroenteritis, hepatitis, encephalitis, and retinitis. CMV disease is much less commonly seen in the autologous HSCT setting.[187] Because of the risk of transfusion-transmitted CMV disease in transplant recipients, "CMV safe" blood products should be provided to CMV-negative transplant recipients.

Serologic screening of blood products is currently the most effective means of reducing the risk of transfusion-transmitted CMV. The rare cases of transfusion-transmitted CMV disease still observed in large part reflect donations made in the preseroconversion window period.[188] Because the seroprevalence of CMV ranges in different communities from 40% to 80%, it is logistically difficult for blood banks to maintain an inventory of CMV-seronegative components.[189] Several studies have demonstrated that leukoreduction can be used as an alternative to serologic screening to provide blood that is "CMV safe."[187,190–195] Although unquestionably efficacious, leukoreduction appears to be slightly inferior to providing seronegative products for the prevention of CMV transmission.[190,196,197] Overall, although transfusion-transmitted CMV remains a problem in the HSCT and solid-organ transplant population, the transmission rates seen using either seronegative or leukoreduced products are far lower than in the past, due in large part to improvements in both surveillance and preemptive therapy.[198]

Transfusion-Associated Graft-versus-Host Disease

Transfusion-associated GVHD (TA-GVHD) is a devastating complication of transfusion that primarily affects immunocompromised patients, including hematopoietic stem cell and solid organ transplant recipients. TA-GVHD occurs when immunocompetent lymphocytes in a blood

product proliferate in the transfusion recipient. The donor lymphocytes attack host organs, including bone marrow, skin, liver, and intestines. TA-GVHD usually becomes clinically apparent 7 to 10 days after transfusion. Patients usually present with fever, skin rash, elevated results on liver function tests, and gastrointestinal symptoms. Severe pancytopenia is often observed. In classical GVHD, the bone marrow is typically spared, because donor and recipient bone marrow are selected to be HLA-compatible. In contrast, TA-GVHD involves immune rejection of host marrow cells, and as a result generally carries a worse prognosis than classical GVHD. TA-GVHD is almost always fatal within 4 weeks of transfusion, with most deaths attributable to bleeding or infection resulting from marrow failure.

No effective therapy for TA-GVHD currently exists, but it is prevented by gamma-irradiation of blood products before transfusion. TA-GVHD was previously reported to occur following blood product irradiation to 1500 rads,[199] and other studies indicated that irradiation to 2000 rads is needed to reduce mitogen-responsive lymphocytes by 5 to 6 logs.[200] Irradiated blood products are now required to receive 2500 rads (25 Gy) to the center of the container, with a minimum dose of 1500 rads (15Gy) to any other point.[201] Cellular blood products are required to be irradiated in the following situations: recipients identified to be at risk for TA-GVHD, donations made by blood relatives of the recipient, and donors selected to be HLA-matched with the recipient.[202]

Chapter 40

Transfusion of the Platelet-Refractory Patient

Thomas S. Kickler

Platelet transfusion therapy has improved over the past 2 decades with new methods for collection, storage, and processing of platelets. With the development of aggressive forms of chemotherapy, organ transplantation, and new strategies to treat aplastic anemia and related bone marrow failure disorders, the clinician relies heavily on the availability of platelet transfusions. Consequently, practitioners of platelet transfusion therapy must know how to use platelet transfusions effectively so that resources are not wasted. This chapter describes the use of platelet transfusions in a variety of medical conditions, especially in patients requiring multiple platelet transfusions. Because refractoriness to platelet transfusions is a serious problem, methods to circumvent or prevent it are also described.

INDICATIONS FOR PLATELET TRANSFUSIONS

In patients with thrombocytopenia, the risk of hemorrhage increases progressively once the platelet count drops below 100,000/μL.[1–3] Many studies have attempted to define the bleeding time or platelet count necessary to achieve hemostasis in surgical patients, with conflicting results.[3–7] Some generalities do exist, however. With normally functioning platelets, most major surgery can be performed safely if the count is maintained in the range of 50,000 to 75,000/mL. A higher range may be necessary for longer and more technically difficult procedures involving extensive incisions or exposure of large surface areas. Performance of surgery on the central nervous system should be done only with platelet counts greater than 100,000/μL.[3] Table 40–1 shows general guidelines for the transfusion of platelets in different clinical situations.

In amegakaryocytic thrombocytopenia, platelet transfusions are given prophylactically or therapeutically and for the performance of invasive procedures. There is considerable interest in trying to define the lowest safe platelet concentration, so that fewer donor exposures occur and limited blood resources are conserved. Physicians have been generally aware that hemorrhage is more common during the most severe stages of thrombocytopenia. A study of 92 consecutive patients treated for acute leukemia between 1956 and 1959 at the National Cancer Institute led to the current prophylactic guidelines. Platelet counts lower than 100,000/μL were associated with an increased risk of bleeding. Patients with platelet counts of 5,000/μL or less manifested gross hemorrhage on approximately one third of days at risk. A platelet count of 20,000/μL or less was associated with moderate bleeding manifestations such as epistaxis and petechiae. Based on these studies, a prophylactic platelet transfusion strategy, using a platelet count of 20,000/μL as the transfusion trigger, has been commonly employed.[8]

More recently, in a randomized study of prophylactic platelet transfusion, Rebulla and coworkers[5] showed that giving transfusions only when the platelet count dips below 10,000/μL can decrease platelet use with only a small adverse effect on bleeding and no effect on mortality. It therefore appears that, with amegakaryocytic thrombocytopenia, prophylactic transfusions should be given if the count falls below 5000/μL. At values between 5000 and 10,000/μL, transfusion may be withheld if the patient is stable and if no other conditions make spontaneous bleeding likely.[5] Such conditions include blast crisis, rapidly falling platelet count, anticoagulation with heparin for disseminated intravascular coagulation (DIC), drugs that affect platelet function, uremia, and recent invasive procedures, including spinal taps or placement of central venous catheters.[9]

PLATELET TRANSFUSION REFRACTORINESS

Failure to achieve an expected increment with a platelet transfusion is called *platelet transfusion refractoriness.* Refractoriness may be caused by an immune or a nonimmune condition. Clinically, one can assess the response to a platelet transfusion by measuring the increment in platelet count 1 to 18 hours after the transfusion. The post-transfusion platelet response should be calculated on the basis of the patient's body surface area in square meters and corrected for the number of platelets transfused. The corrected platelet count increment (CCI) is calculated by the following formula:

$$\text{CCI} = \frac{\begin{bmatrix}\text{body}\\ \text{surface}\\ \text{area } (m^2)\end{bmatrix} \times \begin{bmatrix}\text{platelet}\\ \text{count}\\ \text{increment}\end{bmatrix} \times 10^{11}}{\text{number of platelets transfused}}$$

In general, a successful CCI should be greater than 7500 within 10 to 60 minutes after a transfusion and greater than 4500 if measured 18 to 24 hours after transfusion. It has been suggested that the CCI determined 1 hour after platelet transfusion is a useful indirect measure to document alloimmunization.[2] However, human leukocyte antigen (HLA) antibodies are only one of many factors that influence the CCI at 1 hour. Furthermore, even if platelet antibodies are present, excellent 1-hour CCIs may be achieved.[10] This latter phenomenon may be seen after platelets with weak expression of HLA-B locus antigens are given.[2,3,9]

Table 40–1 **Platelet Transfusion Guidelines**

Platelet products: The benefits of pooled platelets or single-donor platelets are similar; the two products can be used interchangeably. Single-donor platelets from selected donors are used when histocompatible platelet transfusion (i.e., HLA-A and HLA-B antigen matched) are needed.

Prophylactic Platelet Transfusion Thresholds:

Acute leukemia: For adult patients a threshold of 10,000/μL is recommended. Transfusion at higher levels may be necessary in the newborn or in patients with hemorrhage, high fever, hyperleukocytosis, rapid fall in platelet count, or coagulation abnormalities.

Hematopoietic stem cell transplantation: Same as for acute leukemia, with similar exceptions.

Chronic stable severe thrombocytopenia: Many patients can be observed without prophylactic transfusion, reserving transfusion for episodes of hemorrhage or during times of active treatment.

Solid tumors: Evidence supports the benefit of prophylactic transfusion at a threshold of 10,000/μL or less. A threshold of 20,000/μL should be considered for patients receiving aggressive therapy for bladder cancer, as well as for those with demonstrated necrotic tumors.

Surgical or invasive procedures: A platelet count of 40 to 50,000/μL is sufficient to perform major invasive procedures safely, in the absence of associated coagulation abnormalities. Certain procedures, such as bone marrow aspiration/biopsy, can be performed safely with counts <20,000/μL; lumbar puncture in children is safe at platelet counts >10,000/μL.

Immunologic Basis of Platelet Transfusion Refractoriness

Soon after the introduction of prophylactic platelet transfusions, it became apparent that serial transfusion results in decreasing effectiveness in many patients.[10] Through the work of Yankee and others,[11] it is now recognized that transfusion failures result from the induction of alloantibodies to HLA and other antigens. Yankee and coworkers[11] were able to show that most cases of platelet refractoriness could be reversed by the use of platelet transfusions phenotypically matched at the HLA-A and HLA-B loci. It was also recognized that the development of HLA antibodies, as measured by lymphocytotoxic activity, correlated with the development of the immune refractory state.[12] It is now well recognized that the alloimmune response to HLA-A and HLA-B locus antigens is the major cause of post-transfusion alloimmune transfusion failure.

Antibodies to the human platelet-specific antigens (HPAs) only rarely cause platelet transfusion refractoriness. In a large series of patients who received platelet transfusions, only 2% had detectable antibodies to HPAs. Most of these antibodies were found in patients who were also alloimmunized to HLA class I antigens. If HLA-identical platelet transfusions fail, antibodies to the HPAs should be considered. Antibody specificity to the HPAs can be identified by enzyme-linked antiglobulin assay and isolated platelet glycoproteins of different phenotypes.[13,14] In general, few donor centers have a donor population typed for the HPAs, except for those in the HPA-1 system. The recent introduction of DNA-based typing for HPAs permits accurate typing of donors and even thrombocytopenic patients, because lymphocyte-derived DNA is used.[15]

Detection of Antibodies in Platelet Transfusion Refractoriness

Specific identification of alloimmunization can be done by measurement of HLA antibodies using lymphocytotoxicity testing.[16] Serial lymphocytotoxic antibody measurements are helpful in the management of alloimmunization. Some patients have decreases or a loss of lymphocytotoxic antibody, either permanently or transiently, and can be successfully transfused with platelet concentrates.[17] It should be noted that some patients have antibodies to HLA class I and yet do not have platelet transfusion failures. Commercially available solid-phase enzyme-linked immunoassays that detect the presence of immunoglobulin G anti-HLA antibodies with the use of purified HLA antigens prepared from platelet concentrates are available.[18]

HLA Alloantigens and Antibodies

Understanding the HLA system is important so that compatible platelet transfusions may be selected for alloimmunized patients.[19] Only HLA-A and HLA-B antigens have been shown to be important in causing immune-mediated platelet transfusion refractoriness. Two broad types of HLA antibodies are made in response to platelet transfusions. The first type recognizes epitopes unique to a particular HLA allele, referred to as *antibodies to private specificities.* Antibodies to HLA-A2 and HLA-B12 fall into this group. The second type of HLA antibody recognizes more than one gene product. These antibodies recognize structural similarities between gene products (cross-reactive epitopes) or identical epitopes present on gene products of different alleles and are referred to as *antibodies to public epitopes.* Traditionally, HLA serology has placed the greatest emphasis on classification of the private antigens. Recently, more importance has been placed on the clinical importance of public HLA specificities. The best known examples of public specificities are HLA-Bw4 and HLA-Bw6. These antigens are encoded by a diallelic system and are associated with two different groups of HLA-B class I antigens. Other public antigens carried by HLA-B class I antigens have been divided into four cross-reactive groups: HLA-B5, HLA-B7, HLA-B8, and HLA-B12. The observation that the specificity of HLA antibodies in multiply transfused individuals is usually against public epitopes suggests that matching for these public antigens is important. With improved serologic approaches to the identification of specificities to class I HLA antigens, selection of platelets for transfusion may be simplified by relying on public specificities.

CLINICAL FEATURES OF ALLOIMMUNE REFRACTORINESS

In a series reported by Dutcher and colleagues,[20] 42% of 114 patients developed lymphocytotoxic antibody within the first 8 weeks after transfusion. Approximately one fourth of these patients developed antibody within 1 week, suggesting the presence of an anamnestic response, and 75% of responders appeared to have a de novo response. Of those patients who manifested lymphocytotoxic antibody, 17 ultimately lost

antibody despite further transfusions. Of those initial patients who did not respond by developing lymphocytotoxic antibody in the first 8 weeks, 92% remained unresponsive despite continued transfusion therapy. Therefore, the development of an alloimmune response after transfusion seems to be an early event in therapy. Responsiveness or nonresponsiveness to HLA antigens develops during the first weeks of therapy, and this pattern is apparently maintained throughout subsequent therapy.[20]

Antiplatelet Glycoprotein Antibodies

In addition to the phenotypic differences that arise because of polymorphisms in platelet glycoproteins, patients may form antibodies to the entire platelet glycoprotein molecule. For example, individuals who have the Bernard-Soulier syndrome may become immunized to glycoprotein Ib, and those with Glanzmann thrombasthenia may become immunized to glycoprotein IIb/IIIa. Patients who lack these important membrane glycoproteins and require platelet transfusions may become immunized to normal platelets. This results in transfusion refractoriness and significantly complicates the transfusion management of qualitative platelet disorders.[21]

ABO Blood Group Antigens

Platelets have ABO antigens on their surface; some are intrinsically present, and some are adsorbed from the plasma. Although platelets are usually regarded as having only weak expression of A and B antigens, some donors have strong A or B antigen expression that may result in refractoriness to isolated units. The importance of platelet ABO antigens in platelet recovery was clearly demonstrated in 1965 by Aster.[22] After group A platelets were transfused to group O volunteers, the average recovery was 19%, whereas after transfusion with ABO-compatible platelets it was 63%, similar to recovery after autologous platelets. In general, however, less striking differences are seen in practice: increments are only about 20% lower for transfusion with ABO-incompatible compared with ABO-compatible units.[22–25]

Nonimmune Refractoriness

Platelet transfusions may not result in an increment if the stored platelets are defective. This result should be relatively uncommon, given the close scrutiny devoted to quality control of blood products. However, one should remember to consider freshness of a given platelet transfusion as the cause of a single instance of platelet transfusion failure.[2]

Coagulopathy

Disseminated intravascular coagulation has classically been associated with platelet refractoriness. This syndrome is associated with bacterial sepsis, which is common in transfused patients, and with acute progranulocytic leukemia. The quantitative role of DIC in the platelet refractory state has not been well characterized.[2,3]

Splenic Sequestration

Splenomegaly has been shown to be a major cause of platelet transfusion failure. Normally some 30% of a patient's platelet mass is contained within the spleen. With increases in splenic size, up to 90% of circulating platelets can be sequestered in this organ. Characteristically, splenic sequestration is associated with a reduced 1-hour platelet recovery but normal survival.[2,3]

Fever and Infection

Studies by several groups have implicated both fever and infection as a cause for decreased platelet survival. One study noted that platelet transfusion requirements were increased by 50% in febrile patients. This increase may be greater in patients with major infections, particularly DIC.[26,27]

Other Factors

Platelet refractoriness has been reported with a number of medications. Amphotericin in particular has been implicated in decreasing platelet recovery and survival. Similarly, vancomycin has been reported to be a major cause of platelet refractoriness, as have antithymocyte globulin, granulocyte-macrophage colony-stimulating factor, granulocyte colony-stimulating factor, and other interferons. In view of the large number of drugs cancer patients characteristically receive, it would not be surprising if a number of additional agents were implicated in accelerated platelet destruction.[2,26,27]

MANAGEMENT OF THE ALLOIMMUNIZED PATIENT

Because alloimmunization to HLA antigens accounts for the majority of cases of alloimmune platelet transfusion refractoriness, platelets can be selected on the basis of HLA matching.[2,3] Depending on the HLA type of an individual, there may be little difficulty in locating platelets that are identical. In some patients with unusual HLA types, such as in diverse ethnic groups, HLA matching may be more difficult.

Kickler and coworkers[28] studied the effectiveness of HLA matching as the sole method of platelet selection for alloimmunized patients. Of 50 HLA-identical platelet transfusions, 20% were unsuccessful. Of transfusions selected on the basis of crossreactivities without regard to matching of public specificities, 41% (23 of 56) were failures. One third of those transfusions in which one or two antigen-mismatched platelets were used were failures. These observations indicated that matching of platelets on the basis of HLA private antigens is frequently unreliable as a sole criterion. On the other hand, even if patients are alloimmunized, they may receive mismatched platelets and have successful transfusions.[28]

For these reasons, refining the selection process of platelets for alloimmunized patients has been the subject of much investigation. Table 40–2 outlines a practical approach to selection of platelets for the alloimmunized patient that takes into account the importance of HLA matching and platelet compatibility testing. Numerous investigators have evaluated the usefulness of crossmatching a recipient's platelets with those of potential donors. This approach can be readily followed because pheresis platelets are stored for 5 days. By analyzing aliquots of platelets taken from integrally attached tubing segments, compatible platelets can be found in the inventory of stored platelets. Compatible donors may be found even if a patient is broadly alloimmunized.[29,30]

Because providing crossmatched platelets may be difficult or impractical given frequent transfusions and the need to crossmatch against a large number of potential donors, there is much interest in developing methods of pretransfusion

Table 40–2 **Non–Antibody-Specific Approach to Selection of Platelets for Alloimmunized Patients**

Determine human leukocyte antigen (HLA) phenotype and ABO type of the recipient.
Screen patient's serum for lymphocytotoxic antibody or antibodies to human platelet antigens if there is a history of failing HLA-identical platelets.
Select from the donor pool those units with the most compatible HLA antigens and, if possible, ABO systems; alternatively, crossmatch available platelet units without regard to patient or donor HLA type.
Crossmatch the recipient's serum with selected potential donors and select the most compatible unit.

testing, similar to those used to select compatible red blood cells. These procedures are well known to transfusion services and involve phenotyping of donors and recipients and identification of the specificity of antibodies present in a patient's serum. Specifically for platelets, HLA phenotyping of donors and recipients, and identification of the HLA antibody specificities are required. Petz and coworkers[29] extensively evaluated this approach, and it appears to be highly reliable and successful in identifying donors who would ordinarily be excluded if only exact HLA matches were considered. These investigators coined the phrase *antibody specificity prediction* (ASP) method to describe these procedures.

Petz and coworkers[29] reported data on the utility of ASP for 1621 platelet transfusions in 114 persons with platelet transfusion refractoriness. They compared the effectiveness of platelets selected by the ASP method with that of platelets selected on the basis of HLA matching or crossmatching or, if selected components were not available, on a random basis. They concluded that the ASP method was as effective as HLA matching or crossmatching, and that all three methods were superior to the random selection of platelets. Further, in a file of HLA-matched donors, many more potential donors were identifiable by the ASP method than by HLA matching, which makes the acquisition of compatible platelets for alloimmunized refractory patients much more feasible. This approach appears to be logistically simple on a regional basis when the testing is offered by blood centers, and it promises to harmonize the selection of platelets with the selection process used for red blood cell transfusions.

Management of Platelet Transfusion Refractoriness and Bleeding

A variety of approaches have been attempted when no compatible platelets can be found for a patient who is alloimmunized and continues to bleed or may be undergoing invasive procedures.[2,31] Therapeutic modalities have included splenectomy, corticosteroids, plasmapheresis, administration of intravenous immunoglobulin (IVIG), and repeated platelet transfusions. Except for IVIG, there is little evidence that any of these treatments work.

Kickler and coworkers[32] performed a randomized, placebo-controlled clinical trial investigating the use of IVIG in alloimmunized thrombocytopenic patients. In this trial, IVIG was administered at a dose of 400 mg/kg for 5 days. An incompatible platelet transfusion from the same donor was used before and after the administration of IVIG or placebo. Although platelet recovery in 1 to 6 hours was satisfactory in five of seven patients after IVIG treatment, 24-hour survival was not improved in most of them. It could not be excluded that this poor 24-hour survival result was due to nonimmune causes of shortened platelet survival. None of the placebo group (five patients) achieved a satisfactory 1-hour CCI. By *t*-test, the post-treatment mean 1-hour CCI values were significantly greater in those who received IVIG than in the control group.[32]

If all conventional methods fail to increase the platelet count to hemostatic levels, the only remaining alternative that has been tried is continuous transfusion of platelets (massive transfusion). It has been argued that, although the platelet count is not increased, transfused platelets still exert some effect, permitting platelet plug formation or maintenance of endothelial integrity. These arguments are based on clinical observations. In one well-established animal model of alloimmune thrombocytopenia, if the platelet count did not increase above 60,000/μL, capillary leakage or bleeding still persisted.[2,3]

Other Approaches

In uncontrolled studies and in small controlled studies, the antifibrinolytic agents aminocaproic acid and tranexamic acid have been used.[31] The results have been mixed in terms of reduction of microvascular hemorrhage and reduction of platelet transfusion requirements. The differing results probably are related to the small number of patients studied. Immunosuppressive agents, splenectomy, and plasma exchange have not been proven effective.[2,3]

PREVENTION OF ALLOIMMUNIZATION

Reduction of Donor Exposures

Several studies have shown a direct relationship between the number of platelet transfusions and alloimmunization.[33,34] Others have not documented a dose–response relationship.[2] The reasons for these contradictory conclusions are not clear. In part, clinical differences in the study populations, such as the multiparous state of transfusion recipients, may be the main explanation. Another problem in the literature has been the definition of alloimmunization, including the laboratory end point and the method used to measure HLA antibodies. For a primary immune response, 2 to 3 weeks may be required. If sera are not collected over a sufficient interval, an antibody response may not be measured. Alternatively, some patients may lose antibody by the time of testing, contributing to negative responses. The published data are also consistent with the hypothesis that the alloimmune response has a threshold effect. Over a low range of exposure, there may be a dose–response effect. With larger numbers of exposures, further alloimmunization may not develop if tolerance has been established.

Preventive Measures

Results of early animal studies showed that depletion of contaminating leukocytes from donor blood components was effective in preventing alloantibody response to the major histocompatibility complex (MHC).[33] Other approaches, such as inactivation of donor leukocytes by ultraviolet irradiation, provided further evidence of the important role of donor leukocytes in eliciting immune responses to class I MHC antigens. With the development of highly efficient methods to remove leukocytes from blood products, a number of clinical trials were instituted. In general, if fewer than 1×10^6 contaminating leukocytes remained, alloimmunization was reduced by 30% to 50%. Many of these studies in thrombocytopenic patients also showed some success in the use of leukocyte-poor blood components to prevent HLA alloimmunization or platelet transfusion refractoriness. However, the results obtained from a variety of clinical trials have been inconclusive and not reproducible, perhaps because of variability in blood product preparation and heterogeneity in the patient populations studied.

Because of the confusing data, a large multicenter clinical trial was done in the United States. This Trial to Reduce Alloimmunization to Platelets (TRAP) tested the efficacy of transfusion with platelets modified by leukocyte reduction or ultraviolet irradiation or with leukocyte-depleted, single-donor platelets.[34] The results obtained with these modified platelet products were compared with transfusion of platelet concentrates. All patients received leukocyte-depleted red blood cells. A total of 534 patients with acute myeloid leukemia were studied during an 8-week period for the development of platelet alloantibodies. Of patients in the control group, 45% developed HLA antibodies compared with 22% of those in the ultraviolet-irradiated group, 18% in the filtered platelet concentrate group, and 17% in the filtered apheresis group. All three types of treated platelets were associated with a significant reduction in the development of HLA antibodies and alloimmune platelet refractoriness compared with the control group. These maneuvers were effective even though 26% of the patients had received previous transfusions of nontreated blood products. Importantly, none of the treatment maneuvers reduced the rate of alloimmunization to HPAs (6% to 10%). Therefore, this large study documented the usefulness of either leukocyte removal or inactivation by ultraviolet irradiation in the chronically transfused platelet recipient. The use of platelet concentrates derived from whole blood did not increase the risk of alloimmunization compared with single-donor platelets. Several other studies have confirmed these findings.[35]

Chapter 41

Autoimmune Hemolytic Anemias

Leslie E. Silberstein • Melody J. Cunningham

SPECTRUM OF AUTOIMMUNE HEMOLYTIC SYNDROMES

Autoimmune hemolytic anemias refer to a spectrum of disorders in which autoantibodies against antigens on the erythrocyte membrane cause shortened survival of native as well as transfused red blood cells (RBCs). Three categories of antierythrocyte autoantibodies exhibit distinctive serologic properties and result in characteristic clinical disorders (Table 41–1). Immunoglobulin G (IgG) warm autoantibodies attach to erythrocytes at 37°C, IgM cold autoantibodies clump RBCs at cold temperatures, and IgG Donath-Landsteiner antibodies bind to RBC membranes in the cold and cause hemolysis at 37°C; in this chapter, the associated clinical entities are referred to as *warm autoimmune hemolytic anemia* (AIHA), *cold agglutinin disease*, and *paroxysmal cold hemoglobinuria* (PCH), respectively. All of these antibodies are capable of simply attaching to the RBC membrane without having any pathologic effect or inducing fulminant hemolysis.[1] The antibodies may be idiopathic or may develop secondary to another disease process or in response to exposure to a drug.

Historical Background

The first recognized form of hemolytic anemia was PCH, probably because its clinical manifestation, the passage of black urine after exposure to cold, is so striking. Reports of apparent cold-induced hematuria began to appear in medical literature in the mid-1800s. By 1884, the association of PCH with syphilis was noted. In 1904, Donath and Landsteiner determined that an autolysin fixed to the patient's RBCs in the cold and that a heat-labile serum factor lysed the erythrocytes at 37°C.

The first report of cold agglutinin disease appeared in 1918, but the fact that cold agglutinating serum antibodies were found in healthy individuals initially obscured the significance of cold autolysins. In 1937, these cold-reactive antibodies were discovered to occur in much higher, thus pathologic, levels in affected patients. Dameshek and Schwartz established the first experimental model of immune hemolytic anemia, inducing hemolysis by injection of heterologous antierythrocyte antibodies into guinea pigs. Yet the idea of an "autoimmune" form of hemolytic anemia was resisted for several reasons, punctuated by the difficulty in making the diagnosis.

The antiglobulin test, designed to detect nonagglutinating anti-erythrocyte antibodies, was introduced into clinical medicine by Coombs and associates[2] in 1945. Within 1 year, this test was used to diagnose autoimmune hemolytic anemia.[3] In 1954, autoimmune hemolytic anemia in dogs was reported,[4] and in 1958, the first easily bred animal model of the disease, the NZB mouse, was described.[5] This last discovery was a turning point in the development of a scientific basis for the study of autoimmunization.

WARM AUTOIMMUNE HEMOLYTIC ANEMIA

Epidemiology in Children and Adults

The incidence of AIHA is estimated to be approximately 1 in 100,000 adults and less than 0.2 in 100,000 children. The disorder is less common than immune thrombocytopenia.[6] In

Table 41–1 **Characteristics of Autoimmune Hemolytic Anemia (AIHA)**

	Type of AIHA		
Characteristic	**Warm-Reactive**	**Cold Agglutinin Disease**	**Paroxysmal Cold Hemoglobinuria**
Antibody isotype	IgG Rare IgA, IgM	IgM	IgG
Direct antiglobulin test result	IgG Rare C3	C3	C3
Antigen specificity	Multiple, primarily Rh	I/I, Pr	P
Hemolysis	Primarily extravascular	Primarily extravascular	Intravascular
Common disease associations	B-cell neoplasia, lymphoproliferative, collagen-vascular	Viral, neoplastic	Tertiary syphilis, viral

Ig, immunoglobulin.

teenagers and adults, AIHA is more common in women than in men. In children, boys are somewhat more affected than girls. AIHA occurs at all ages but more commonly in midlife. In pediatric cases, the mortality is less than 10% and primarily occurs in adolescents with a chronic refractory course.[7]

Approximately half of cases of AIHA are idiopathic. In children, AIHA in patients younger than age 2 and older than age 12 is more likely to have a chronic unremitting course.[8] Some cases are induced by drugs, and others occur concomitantly with another autoimmune disease or malignancy. A substantial proportion of cases develop in patients with systemic lupus erythematosus (SLE), B-cell lymphomas, or chronic lymphocytic leukemia (CLL). A number of other diseases have also been complicated by AIHA, but only as unusual exceptions.[9] Treatment of the underlying process can often resolve the AIHA. In other instances, presumably by affecting T cells more than B cells, drugs induce a disturbance in immunoregulatory T cells and trigger the onset of hemolytic anemia.[10,11]

As more diseases, malignant and nonmalignant, are treated with bone marrow transplantation (BMT) and peripheral blood stem cell transplantation (PBST), the numbers of cases of post-transplant autoimmune hemolysis are expected to increase. An overall 2.6% incidence was reported in a recent study in post-BMT patients. A 5% incidence was found in those patients surviving 6 months.[12] The timing of development of post-BMT AIHA appears to depend on the antibody mediating the hemolysis, possibly because IgM reconstitutes earlier than IgG. In this clinical setting, three distinct mechanisms can mediate the hemolysis. Investigations to determine the etiology of hemolysis will appropriately direct therapy, expected duration, and prevention.[13] The three possibilities are true autoimmune hemolysis, immune hemolysis mediated by passenger lymphocytes, and immune hemolysis in the setting of chimerism and major blood group mismatch[13] (Table 41-2).

Pathophysiology

Attachment of autoantibody to the surface of the RBC may lead to intravascular or extravascular hemolysis. The pathologic effect is determined by the class or subclass as well as the avidity of the antibody attached and the extent to which complement is activated. IgA, IgM, IgG1, and IgG3 can all fix complement, although IgA is a rare cause of AIHA.[14] If complement is activated through the C5 to C9 membrane attack complex, intravascular hemolysis occurs.[15] The RBCs coated with simply antibody or complement component C3b are phagocytized by macrophages and destroyed extravascularly in the spleen or liver, respectively. Cells coated with IgG are destroyed primarily in the spleen; those with IgM, in the liver.[16]

The interaction of macrophages with RBCs coated with IgG or C3b (or both) occurs through receptors specific for the Fc portion of IgG (especially IgG1 and IgG3) and for C3b.[17,18] The presence on the erythrocyte membrane of both IgG and C3b accelerates immune clearance,[19–21] suggesting that the Fc and C3b macrophage receptors act synergistically.

Red Blood Cell Injury

The opsonized RBC may be phagocytosed and destroyed entirely by macrophages. Alternatively, proteolytic enzymes may digest part of the membrane surface, producing spherocytes. The spherocytes are less deformable and consequently are hemolyzed in the spleen. The predominant mechanism of destruction of erythrocytes coated with IgG with or without C3b occurs extravascularly in AIHA. The amount of immune clearance is also mediated by the entire reticuloendothelial system; thus, viral or bacterial infections may exacerbate hemolysis.[22] In vitro assays of the ability of blood monocytes from patients with viral infections to phagocytose immunoglobulin-coated RBCs have shown marked deviations from normal.[23,24]

Clinical Findings

The clinical findings in AIHA are variable. They are determined by the rate of hemolysis and by the abilities of the body to process breakdown products and of the bone marrow to mount a reticulocytosis. Some of the signs are associated with hyperdynamic circulation secondary to anemia and a concomitant decrease in oxygen-carrying capacity. They include hepatomegaly and, in more severe cases, pulmonary edema, lethargy, and obtundation. Splenomegaly can also occur

Table 41–2 **Post-Transplant Immune Hemolysis**

Immune Hemolysis	AIHA	Passenger Lymphocyte	ABO Rh Mismatch
Mediated By	Donor lymphocytes	Donor memory B cells in solid organ or stem cells	Recipient Ab
Directed Against	Donor RBCs	Recipient RBCs	Donor RBCs
Cause	T-cell dysfunction; immunomodulatory medications	GVHD-like reaction with production of Ab	Preformed Ab or Ab formed in response to donor tissue
Onset	2–25 months post-transplant	5–17 days	Acute; timing depends on preformed or newly formed Abs
Duration	Variable, depending on response to therapy	Usually resolves in 3 months	
Treatment Options	Same as idiopathic AIHA	Compatible RBC transfusions; plasma or RBC exchange	Compatible RBC transfusion; immunosuppression
Prevention	None known	Prophylactic donor-compatible RBC transfusions	Removal of recipient Ab by plasma exchange or donor RBC purge

AIHA, autoimmune hemolytic anemia; GVHD, graft-versus-host disease; RBC, red blood cells.

from an increase in white pulp. Other signs and symptoms, such as jaundice, fever, and renal insufficiency, are caused by the breakdown products and subsequent vasoconstriction. It has now been demonstrated that decreased renal perfusion, not injury due to free hemoglobin, is the mechanism leading to renal insufficiency.

Autoimmune hemolytic anemia may have a fulminant presentation, with rapid onset of profound anemia, or may develop gradually, with concomitant physiologic compensation. Occasionally, unsuspected AIHA is diagnosed through a positive direct antiglobulin test (DAT) result in an anemic patient who has been referred for transfusion. The presence of lymphadenopathy, fever, hypertension, renal failure, rash, petechiae, or ecchymoses necessitates careful investigation for an underlying malignancy or collagen vascular disease.

Laboratory Evaluation

Direct and Indirect Antiglobulin Tests

It can be difficult to distinguish AIHA from other forms of hemolytic anemia on the basis of laboratory data. The positive result of a DAT, also known as the *Coombs' test*, is considered pathognomonic of immune-mediated hemolysis. The test detects the presence of IgG or complement bound to the RBC membrane (Fig. 41–1). Severe disease usually produces a strong DAT response, but this finding does not always correlate with the degree of hemolysis.[1] The indirect antiglobulin test (IAT; indirect Coombs' test), which detects the presence of antibodies in the patient's serum, usually has a positive result in AIHA (Fig. 41–2).

A positive DAT result is occasionally noted in a healthy person without anemia or evidence of hemolysis.[25] Conversely, patients with known AIHA may have a negative DAT result; this latter finding can be caused infrequently by laboratory error or by the presence of IgA, IgM, or low-affinity IgG autoantibodies.[26]

More commonly, the test is not sensitive enough to detect small numbers of erythrocyte-bound IgG molecules; this occurs most often in AIHA associated with lymphoma or CLL. If the DAT result is positive, specific reagents are required to identify the erythrocyte-bound protein.

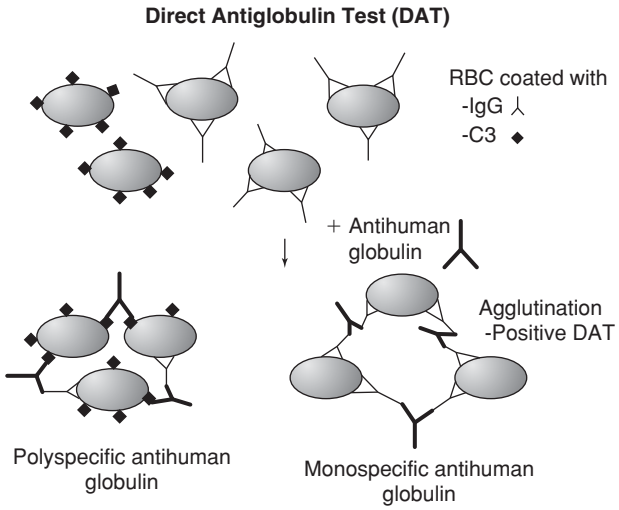

Figure 41–1 Direct antiglobulin test (DAT). C3, complement component 3; IgG, immunoglobulin G; RBC, red blood cell.

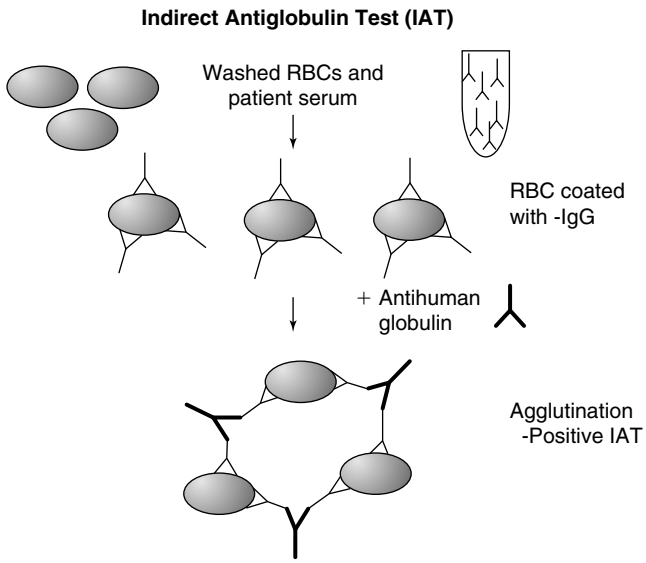

Figure 41–2 Indirect antiglobulin test (IAT). IgG, immunoglobulin G; RBC, red blood cell.

In approximately 80% of patients with AIHA, the autoantibodies are present in serum as well as on RBC membranes.[27] IAT detects the presence of these serum antibodies in the patient's serum. These may be autoantibodies in a patient with AIHA or they may be alloantibodies induced by blood transfusion or maternal-fetal incompatibility. Alloantibodies, present only in the serum, have specificity for RBC antigens not present on the patient's erythrocytes. The DAT result is therefore negative in alloimmunization as long as the patient has not recently been transfused with RBCs that have the target antigen. In the setting of a recent transfusion, the alloantibodies may bind to recently transfused RBCs, yielding a positive DAT result.

Other Supportive Laboratory Investigations

It is difficult to distinguish intravascular from extravascular hemolysis. The hemoglobin, hematocrit, lactate dehydrogenase (LDH), bilirubin, and haptoglobin values are similarly affected in both types of hemolysis. A significant urine hemosiderin level can indicate intravascular hemolysis yet often appears too late to be a helpful clinical tool. An unchanged hemoglobin or hematocrit value obtained within 4 hours after a transfusion of RBCs is an indicator of intravascular hemolysis. The intravascular destruction occurs so rapidly that no evidence of transfusion is reflected in the laboratory values. Intravascular hemolysis is important to recognize, because the patient may require greater supportive care to treat the anemia and consequent organ injury from intravascular hemolysis.

Like clinical symptoms, laboratory findings reflect the intensity of the hemolytic process as well as the ability of the body to process the RBC breakdown products and of the bone marrow to respond to the anemia. In fulminant cases, with an RBC life span of less than 5 days, the anemia is severe and erythropoiesis increases eight- to tenfold. As a result, the reticulocyte count rises, sometimes to levels greater than 40% of RBCs. If the regenerative capacity of the bone marrow lags only slightly behind the rate of RBC destruction, a mild anemia with an elevated reticulocyte count results. Between these extremes are many variations. Inspection of the blood smear in a typical case reveals polychromatophilia,

spherocytes, a few fragmented RBCs, nucleated RBCs, and, occasionally, erythrophagocytosis. Examination of the bone marrow, which is rarely indicated, shows erythroid hyperplasia, often with megaloblastoid features. Occasionally, RBC autoantibodies or parvovirus B19[28] cause reticulocytopenia and dyserythropoiesis, thereby contributing to the severity of anemia.[29]

Patients with severe hemolytic anemia and markedly increased erythropoiesis occasionally experience folate deficiency and frank megaloblastosis. The growth of hematopoietic tissue in the bone marrow also leads to moderate increases in the white blood cell and platelet counts. The absence of reticulocytosis does not exclude the diagnosis of AIHA but portends a serious prognosis.[30–33] In addition, reticulocytopenia may represent excessive apoptosis of erythroblasts.[30,31,33,34] Presumably as a result of destruction of young erythrocytes by the autoantibody, the reticulocytopenia aggravates the severity of the anemia and increases the need for RBC transfusions.

Therapy

General Principles

The severity of AIHA may range from indolent to life threatening. The impetus to initiate treatment, as well as the determination about whether the treatment required is immediate transfusion or an attempt to modulate the immune system's production of autoantibody, must be based on a thorough appraisal of symptoms and the extent of the clinical compromise.

Rapidly developing anemia with a hematocrit less than 20% requires urgent management. In less aggressive forms of the disease, however, it may be prudent to allow physiologically compensated anemia rather than to institute treatment. The management of AIHA depends in part on whether the disease is primary or is secondary to such disorders as a B-cell malignancy or SLE.[35,36] This, too, demands a careful assessment before any treatment begins. In some cases of AIHA secondary to lymphoma or CLL, the pathogenic autoantibody (usually monoclonal) is secreted by the neoplastic B cells. Combination chemotherapy or irradiation of the underlying malignancy often brings the hemolytic anemia under control.[37–39]

In other cases, however, the autoantibodies (usually polyclonal) do not originate from the B-cell neoplasm but probably result from abnormal immune regulation instigated by the neoplastic B cells. Treatment of the latter type of secondary AIHA with immunosuppressive agents may improve the anemia but may also trigger an exacerbation.[40] Multiple chemotherapeutic agents and immunosuppressive medications interfere with T-cell function and can thus trigger autoimmune processes in general and AIHA specifically. Fludarabine and cladribine given as therapy for CLL have been demonstrated to precipitate autoimmune processes by interfering with the balance of T- and B-cell functions.[11]

The ultimate goal of therapy is control of the B-cell populations that secrete pathogenic autoantibodies. However, so little is known about such cells[41,42] that the currently available therapy is, by default, nonspecific and often aimed at reducing RBC clearance by macrophages. The desired therapeutic effect is eradication of the abnormal hemolytic process, not reversal of the serologic abnormalities. Indeed, DAT results often remain positive in the presence of a hematologic response.

BOX 41–1 ***Transfusion Therapy and Autoimmune Hemolysis***

There are times when a patient requires transfusion of incompatible RBCs or when transfusion must occur before completion of the blood bank evaluation. Autoimmune hemolytic anemia always complicates and prolongs the blood bank evaluation, which may take up to 24 to 48 hours to complete. It is imperative, however, that the patient receive RBCs expeditiously, *even though they are crossmatch-incompatible*, if the hematocrit is not stabilized or cardiac or cerebral function is compromised. In these situations, the patient should be very closely monitored and should receive the smallest volume of blood necessary to alleviate the life-threatening symptoms.

Transfusion

Some cases of AIHA may be life threatening and may necessitate transfusion with RBCs (Box 41–1). It is important to recognize that, in the majority of cases, the patient receives crossmatch-incompatible blood.[43–46] The presence of autoantibodies complicates and prolongs the evaluation performed by the blood bank. In situations of fulminant hemolysis, transfusion of incompatible blood or transfusion performed on an emergency basis before completion of the evaluation may be imperative and lifesaving. Severe anemia may cause high-output cardiac failure and subsequent pulmonary edema, somnolence, and even obtundation, which require immediate intervention with RBC transfusion. The hemoglobin level at which these symptoms occur varies according to the rate of fall of the hemoglobin level, the capacity for cardiac compensation, and other underlying clinical features. Occasionally (1% to 2% of cases), relative specificity of the autoantibodies can be demonstrated. This specificity usually occurs within the Rh system, and RBCs lacking the corresponding Rh antigen survive better in vivo than those that express the antigen.[47–50] Specificities of IgG autoantibodies for multiple other blood groups have been described.[51]

In addition, the blood bank must look for alloantibodies that may be masked by the autoantibodies. Alloantibodies, usually with specificity for the Rh or Kell blood group systems, occur in approximately 30% of patients with AIHA who have a history of blood group immunization by maternal-fetal incompatibility or previous transfusions.[52–54] The nonspecific serum autoantibodies that react with nearly all normal RBCs must be removed to ensure that no concomitant alloantibodies are present. An adsorption test is performed, using either the patient's cells or cells of known phenotype to absorb the autoantibodies from the serum—a process known as *autologous adsorption* or *heterologous adsorption,* respectively.

These tests are not performed by all laboratories and should not be required before transfusion of a patient in need. However, standard antibody detection and identification tests with both the patient's serum and an eluate prepared from the patient's cells should be performed whenever possible. Titration of the eluate and the serum against RBCs of various Rh phenotypes can indicate an autoantibody specificity (or preference) within the Rh system. Any such specificity should be respected in the selection of donor units.[55,56]

Red blood cell substitutes have been transfused in a few situations of severe hemolytic anemia and have demonstrated benefit to the patients.[57,58] Further investigation of

these substitutes is necessary to determine their efficacy and safety. They could potentially be of benefit in the short-term emergent situation when the presence of underlying alloantibodies cannot be ruled out or when the hemolysis is so brisk that transfusion of least incompatible cells does not result in any increase in hemoglobin and thus in oxygen-carrying capacity.[59]

Corticosteroids

Corticosteroids are the first line of treatment for most patients with symptomatic, unstable AIHA, either idiopathic or secondary. The clinical response to prednisone results primarily from its ability to disable macrophages from clearing IgG- or C3b-coated erythrocytes. Corticosteroids interfere with both the expression and function of macrophage Fc receptors. This interference is probably the earliest, and perhaps even the primary, mechanism in the ability of steroids to diminish the immune clearance of blood cells.[60–63] Prednisone can also reduce autoantibody production, but only after several weeks of therapy.

The side effects of corticosteroids often preclude the long-term use of high-dose therapy. The cushingoid features that develop can lead to noncompliance, especially in adolescents. The associated osteoporosis and immunosuppression as well as the risk of gastric bleeding may warrant discontinuation of therapy.

Splenectomy

Splenectomy has been used as therapy for AIHA for many years.[64] Indications for splenectomy include failure to respond to prednisone, need for prednisone dosages higher than 10 to 20 mg/day, and intractable corticosteroid side effects. The procedure can be highly effective, presumably through removal of the major reticuloendothelial site of RBC destruction; an animal model demonstrated that IgG-coated RBCs are removed almost exclusively by the spleen.[60] In addition, the procedure eliminates many phagocytosing macrophages and autoantibody-producing B cells.

In most young adults with chronic AIHA, the question of splenectomy arises almost inevitably. However, in an elderly patient with a stable but incomplete remission, maintenance therapy with prednisone at a dose of 10 mg/day for an indefinite period may be the better alternative. There is a slight risk that overwhelming sepsis by encapsulated organisms may develop immediately and up to 25 years after splenectomy.[65] The risk is higher in children, especially those younger than age 6, so a conservative approach to splenectomy is prudent in this age group. The risk of overwhelming sepsis is lessened by immunization with pneumococcal and meningococcal vaccines, which are optimally administered at least 2 weeks preoperatively, and by the prompt use of antibiotics for febrile illness.[66] The *Haemophilus influenzae* series of vaccines should also be completed in children before splenectomy.

The response to splenectomy does not correlate with the age of the patient, the presence or absence of an underlying B-cell disorder, the strength of the antiglobulin test result, prior response to prednisone, or the pattern of sequestration of chromium 51 (^{51}Cr)-labeled RBCs. Between 50% and 60% of patients with classic AIHA have a good to excellent initial response to splenectomy. They will need less than 15 mg/day of prednisone to maintain an adequate level of hemoglobin.[67] Information regarding the clinical implications of an accessory spleen in AIHA is meager. Faced with such a rare finding in a patient with relapse, many hematologists would recommend its removal. The role of splenectomy in patients with mixed IgG, IgM, or mixed cold- and warm-reactive IgG antibodies is unclear.

Rituximab Therapy

Rituximab, a chimeric anti-CD20 monoclonal antibody with a well-established, favorable safety profile, has possibilities for widespread clinical application in autoimmune disease in general and AIHA specifically.[68,69] Rituximab induces cell death through complement-dependent lysis, antibody-dependent cellular toxicity, and cellular apoptosis.[68] Although plasma cells, fully differentiated B cells, are CD20-negative, the response rates of patients with AIHA and thrombocytopenia suggest that earlier CD20-positive B cells are producing antibody or that other as-yet not clearly delineated effects of rituximab are effecting the disease remission. Reports that rituximab induces remission in patients with idiopathic thrombocytopenic purpura within 1 week of first infusion suggest that the mechanism of action may involve more than elimination of B cells.[69]

The efficacy and safety of rituximab have been demonstrated in multiple large trials in adult patients with non-Hodgkin's lymphomas.[69] Infusion-related side effects, including fever, respiratory distress, and hypotension, are reported to occur in a small population of lymphoma patients.[69–71] No side effects have precluded completion of planned therapy in patients with autoimmune disease.[72] The occurrence and severity of side effects seem to be related to B-cell level and, thus, tumor burden.[70] It is anticipated and has been demonstrated that the side effect profile will be even more favorable in patients with autoimmune disease who have a lower level of B cells.[73]

No large, prospective trials have studied the efficacy and safety of rituximab in patients with warm AIHA. However, the results of multiple case reports, case series, pilot studies, and small therapeutic trials indicate that rituximab warrants further study in patients with autoimmune disease and have prompted some experts in the field to attempt a trial of rituximab prior to splenectomy in warm AIHA. The literature reveals successful use of anti-CD20 treatment in multiple autoimmune diseases.[6,7,74–79]

Rituximab Therapy: Mechanism(s) of Action

Rituximab's mechanism of action appears to be multifaceted, complex, and incompletely understood. It is known that it induces cell death through complement-dependent lysis; antibody-dependent cellular toxicity; antibody-dependent phagocytosis mediated by Fc, complement, and phosphatidylserine receptors; direct antibody effects of CD20 ligation leading to inhibition of proliferation, apoptosis, and sensitization to chemotherapy; and induction of active immunity.[68] Although plasma cells are CD20-negative, the response rate of patients with AIHA and thrombocytopenia suggest that earlier, CD20-positive B cells are producing antibody or that other as-yet not clearly delineated mechanisms are effecting disease remission. Reports that rituximab induces remission in patients with AIHA within 1 to 3 weeks of first infusion suggest that the mechanism of action may involve more than elimination of B cells. Table 41-3 summarizes the case reports and small case series of patients with AIHA treated with rituximab.

Table 41–3 **Summary of Studies and Case Report Data for Rituximab for AIHA**

Number of Patients/ Disease	Rituximab Dose	Dosing Schedule	% Response	Previous Regimens*	Splenectomy	Follow-up Period
15 pediatric/idiopathic[79]	375 mg/m^2	Weekly × 2–4	87 (13/15)	Two or more S, C, I, CyA, Az	2/15	7–28 months
1 pediatric/SLE,[78] idiopathic[158]	375 mg/m^2	Weekly × 2	100 (2/2)	S, C, I, CyA	0/2	5–7 months
6 pediatric/idiopathic[77]	375 mg/m^2	Weekly × 4 Weekly × 12 (2pt)	100 (6/6)	S, I, Ph, CyA, Az	2/6	15–22 months
4 pediatric/idiopathic[159]	375 mg/m^2	Weekly × 4–6	100 (4/4)	S, V, CyA, Az, I, C, T	2/4	3–14 months
1 pediatric/idiopathic[160]	375 mg/m^2	Weekly × 4 then repeat	100 (1/1)	S, I, C, CyA, ATG, Ph, Az	Yes	19 months
3–1 CAD, 2 WAIHA[161]	375 mg/m^2	Weekly × 4	33 (1/3)	S, C, Az	0/4	96 months

*Regimens: ATG, antithymocyte globulin; Az, azathioprine; C, cyclophosphamide; Ch l, chlorambucil; Cl, cladribine; CyA, cyclosporine; I, intravenous immune globulin; IFN, interferon; MM, mycophenolate mofetil; MP, mercaptopurine; Ph, plasmapheresis; S, corticosteroids; T, tacrolimus; V, vincristine.

Intravenous Immune Globulin

Intravenous immune globulin (IVIG) has been found effective in the management of selected cases of AIHA. The soluble IgG in the material may lengthen the life span of IgG-coated RBCs by saturating Fc receptors on macrophages. In a study of patients who had AIHA associated with lymphoproliferative disorders, a long-term benefit was observed with a maintenance dosage schedule of intravenous IgG every 21 days. A decrease in antiglobulin titer was found in these patients, suggesting a mechanism other than blockade of Fc receptors by intravenous IgG.[80] The mechanism of action of IVIG has been further elucidated by Samuelsson and colleagues.[81] They investigated the mechanism of protection in a murine model of immune thrombocytopenia that may have relevance to mechanism of action in other autoimmune diseases. Their model demonstrated that the inhibitory Fc receptor FcγRIIB was necessary for IVIG to confer protection against platelet destruction.[81] This finding suggests that modulation of inhibitory signals in macrophages could possibly be involved in autoimmunity and could be investigated as therapeutic targets in other autoimmune diseases, such as AIHA.

Immunosuppressive Therapy

Most experience with immunosuppressive drugs in the treatment of AIHA has been with alkylating agents (cyclophosphamide and chlorambucil) and thiopurines (azathioprine and mercaptopurine).[82] The basis for the clinical use of these drugs is their inhibitory effect on the immune system, possibly affecting both B cells and T cells.[83,84]

Cyclophosphamide and azathioprine, like prednisone, can induce numerous side effects. The early side effects include bone marrow suppression and impairment of the immune response (particularly T cell–mediated immunity) that occur concomitantly with therapy. After sustained administration, cyclophosphamide may damage ovarian function, inhibit spermatogenesis,[85–88] and cause bladder fibrosis.[89] Acute myeloid leukemia can develop years after administration of this drug.[83] By contrast, the prolonged use of azathioprine has not been associated with a statistically significant increase in malignant diseases. All of these considerations mandate careful monitoring of any patient treated with either cyclophosphamide or azathioprine.

Cyclosporine, a powerful T-cell modulator, has been used alone and in combination to elicit successful and sometimes durable remission in patients with AIHA and Evans's syndrome.[90] Cyclosporine and other immunosuppressive agents are discussed here and have been reported in the literature. However, their long-term use is not recommended, because the benefits do not usually offset the side effects inherent in the prolonged use of these agents.

Plasma Exchange

Because a single-volume plasma exchange replaces only about 60% of the patient's plasma volume, its therapeutic advantage lies in the removal of plasma antibodies to IgG, IgM, or both, which mediate the hemolysis. Unfortunately, continuous antibody production and the large extravascular distribution of IgG limit the long-term efficacy of plasma exchange in IgG-mediated AIHA. On cessation of therapy, the rate of return to pretreatment levels of autoantibody depends on the rate of autoantibody production.[91] However, there are some reports that this modality is efficacious in IgG-mediated disease.[92] Occasional dramatic responses have been reported in patients being prepared for surgery or when plasma exchange was used as a temporizing measure after initiation of immunosuppressive therapy.[92,93] This therapy is reserved for patients in critical condition whose AIHA is unresponsive to transfusion because of rapid destruction and clearance of the RBCs.

COLD AGGLUTININ DISEASE

Cold agglutinin disease refers to a group of disorders caused by anti-erythrocyte autoantibodies (e.g., cold agglutinins) that preferentially bind RBCs at cold temperatures (4°C to 18°C) and may or may not induce hemolysis. Virtually all sera from healthy individuals contain low-titer cold agglutinins, which are regarded as benign or harmless RBC autoantibodies and are considered polyclonal. Similarly, cold agglutinins that arise after certain infections are also polyclonal and usually benign; in rare cases, a transient form of cold agglutinin disease ensues. By contrast, monoclonal cold agglutinins are generally pathogenic and are derived from clonal B-cell expansions (as in idiopathic or chronic cold agglutinin disease), which may be a prelude to frank lymphoma.

Chronic Cold Agglutinin Disease

The most common type of cold agglutinin disease, a chronic form characterized principally by a stable anemia of moderate severity and attacks of acrocyanosis precipitated by exposure to cold, constitutes about one third of all cases of immune hemolytic anemia. Cold agglutinins cause the cardinal abnormalities of the disease. The acrocyanosis stems from intra-arteriolar agglutination of erythrocytes in the relatively cool tips of the fingers, feet, ear lobes, and nose. The occurrence of this hemolytic anemia depends on the capacity of the cold agglutinins to initiate activation of the complement cascade on the surface of the RBC. Most patients with chronic cold agglutinin disease are in the fifth to eighth decade of life and have a B-cell neoplasm or lymphoma, Waldenström macroglobulinemia, or CLL. The cold agglutinin in cases secondary to such diseases is monoclonal, almost always IgMκ, and may show up as a monoclonal band in the γ region of the serum protein electrophoretic pattern. In the absence of a B-cell neoplasm, the spleen and lymph nodes are rarely enlarged; therefore, the finding of splenic and lymph node enlargement warrants a search for the neoplasm.

Transient Cold Agglutinin Disease

A second type of cold agglutinin disease, usually acute and always self-limited, occurs as a rare complication of several infectious diseases, most notably *Mycoplasma pneumoniae* infection and infectious mononucleosis. Patients with this form of cold agglutinin disease are therefore much younger than those with chronic cold agglutinin disease. The onset is abrupt, occurring as the infection wanes, and the anemia can be severe. Cold agglutinin titers are moderately elevated, and the cold agglutinins are polyclonal. Often, these polyclonal cold agglutinins coincide with high-titer warm-reactive IgG RBC autoantibodies.

ANTIGENIC TARGETS OF COLD AGGLUTININ DISEASE

The antigenic specificity of cold agglutinins is usually identified from their degree of reactivity with RBCs from adults (blood group I) and from cord blood (blood group i). The cold-reactive autoantibody produced after some cases of *M. pneumoniae* infection has anti-I specificity,[94] whereas the antibody in infectious mononucleosis frequently, but not always, has anti-i specificity.[95,96] Additional specificities have been identified by tests with rare adult RBCs that lack the I-antigen or with enzyme-treated erythrocytes. Rarely, cold agglutinins are specific for the A blood group antigen.[46]

Laboratory Evaluation

The usual laboratory findings in hemolytic anemia (i.e., anemia, reticulocytosis, polychromatophilia, spherocytosis, erythroid hyperplasia in the bone marrow, and elevations in serum bilirubin and LDH levels) are generally not striking in chronic cold agglutinin disease. Hemagglutination may be visible to the unaided eye in blood drawn from a patient with cold agglutinin disease and can interfere with automated blood counts. The anemia is often mild and stable, because the C3b inactivator in serum limits the extent of cold agglutinin–induced complement activation on the erythrocyte membrane. Exposure to cold may greatly augment the binding of cold agglutinins, however, exceeding the restraints of the inactivator system. That occurrence can lead to a sudden drop in hematocrit value, with complement-mediated intravascular hemolysis and renal failure.

In a distinctive subset of patients with aggressive cold agglutinin disease, the cold agglutinin titer is relatively low but the autoantibody has a high thermal amplitude. Recognition that a patient has this variant of cold agglutinin disease is important because it may respond to prednisone,[62] whereas high-titer cold agglutinin disease usually does not.

In typical cases of chronic cold agglutinin disease, the cold agglutinin titer is very high ($>1{:}10^5$ and occasionally $>1{:}10^6$). The antibodies are most reactive in the cold, and hemagglutination disappears as the temperature rises toward 37°C. In some cases, however, the antibody is reactive at relatively high temperatures and occasionally even at 37°C. The reactivity of the cold agglutinin at high temperatures (i.e., its thermal amplitudes), not the titer of the antibody, most accurately predicts the severity of the disease. The DAT result is positive because of erythrocyte-bound C3d, but results of tests with anti-IgG reagents are negative. The result of the IAT, which is conducted at 37°C, is negative. In addition to monoclonal IgM cold agglutinins, IgG-IgM mixed cold agglutinins have been reported.[97–99] Besides the usual high titers of IgM cold agglutinins, some patients with cold agglutinin disease have low titers of IgG and IgA cold agglutinins.

Cold agglutinins are not cryoglobulins. The latter are most often monoclonal IgM immunoglobulins that, in the cold, either self-associate and precipitate from solution (type I cryoglobulinemia) or precipitate as complexes with polyclonal IgG molecules (type II cryoglobulinemia, often due to a monoclonal IgM rheumatoid factor). Type III cryoglobulins consist of a mixture of polyclonal IgM and polyclonal IgG immunoglobulins. The clinical manifestations of the cryoglobulinemic syndromes are highly variable: type I and type II cryoglobulinemias occur in B-cell neoplasms (Waldenström macroglobulinemia, multiple myeloma, lymphoma, and CLL); type II and type III cryoglobulinemias can produce a picture of immune complex–mediated vasculitis, with vascular purpura, arthritis, and nephritis as the dominant complications. In occasional patients, the cryoglobulin can also be a cold agglutinin.[100–103]

Pathophysiology

The pathogenic IgM autoantibody in cold agglutinin disease is highly efficient in activating the classic complement pathway on the erythrocyte membrane.[36,104] However, the thermal dependency of the antibody constrains its pathogenic effects. The autoantibody rapidly elutes off RBCs at 37°C, the temperature of the visceral circulation, but in the cool peripheral circulation of the hands and feet, the cold agglutinin remains on the erythrocyte membrane for at least a few seconds. That amount of time is sufficient to activate the complement cascade to the stage of C3b, which adheres to the RBC after it reenters the central circulation. In the hepatic circulation, C3b-positive RBCs encounter macrophages with receptors specific for C3b[19,105,106]; however, C3b sensitization is only a weak signal for the activation of phagocytosis—the hepatic clearance of C3b-coated RBCs requires 500 to 800 C3b molecules per RBC. As a result, many C3b-positive RBCs escape unharmed into the systemic circulation, where they come under the influence of the regulatory proteins of the complement system. The C3b inactivator system degrades C3b into C3dg, C3d, or both. The result is a cohort of erythrocytes coated with C3d but not with the IgM autoantibody.[107] Macrophages bind to C3d with even lower avidity than to C3b, thus the C3d-positive erythrocytes tend to have near-normal survival in vivo despite a heavy coating with that degradation product of C3.[108,109] It is important to recognize that if transfusion is necessary, the transfused cells will not have the protection conferred by C3d and therefore may be rapidly lysed.[109]

These limits on the pathogenicity of cold agglutinins account for the subdued hematologic picture in most patients with cold agglutinin disease. If, however, the regulatory C3b inactivator proteins are impaired, limiting cleavage of RBC-bound C3b, or if the production of IgM autoantibodies with a high thermal amplitude is impaired, permitting completion of the complement cascade in the visceral circulation, severe extravascular hemolysis can occur. Several patients with high titers of IgA cold agglutinins have been reported. Such cases are not associated with cold agglutinin disease, which may relate to the lack of complement activation by IgA antibodies.[109–118]

Therapy

Chronic Cold Agglutinin Disease

Therapy for the cold agglutinin syndromes depends on the gravity of the symptoms, the serologic characteristics of the autoantibody, and any underlying disease. In the idiopathic, or primary, form of chronic cold agglutinin disease, prolonged survival and spontaneous remissions and exacerbations are not unusual. The anemia is generally mild, and the simple measure of avoiding exposure to cold temperatures can avoid exacerbations, especially if the cold agglutinin responsible has a low thermal amplitude. Prednisone has been beneficial in rare cases in which there are relatively low titers of cold agglutinins of a high thermal amplitude or an IgG cold-reactive antibody is produced. However, prednisone is not

useful therapy in most patients with primary IgM-induced cold agglutinin disease, and its administration should not be undertaken lightly, given the chronicity of the disease.[119,120] Plasma exchange may help as a temporary measure in acute situations.[93] Splenectomy is usually ineffective because the liver is the dominant site of sequestration of RBCs heavily sensitized with C3b. However, rare cases in patients with enlarged spleens have responded to splenectomy; in some of these patients, a localized splenic lymphoma was found, whereas in others, only lymphoid hyperplasia was evident.

It is essential to seek evidence of a B-cell neoplasm before therapy for chronic cold agglutinin disease is initiated. Oral alkylating agents (chlorambucil or cyclophosphamide) help many patients with the secondary form of cold agglutinin disease because of their effect on the B-cell neoplasm, but only occasionally do they benefit patients with the primary form of the disease.[121,122] When cold agglutinin disease is part of an established B-cell malignancy, the severity of hemolysis often waxes and wanes in parallel with the activity of the neoplasm.

Patients with IgM-mediated hemolysis can be dramatically helped with plasma exchange. Because of its large size, the antibody is located primarily in the intravascular space and is efficiently removed by plasma exchange. Some patients with Waldenström macroglobulinemia are maintained over the long term with this therapy.

A recent publication of a prospective, phase II study of patients with primary cold agglutinin disease reported a 54% response rate in 27 patients treated with 37 courses of rituximab. Some of the patients who did not respond to the first course of four weekly doses of rituximab were treated with a combination of rituximab and interferon-α. Of the responses, one patient achieved complete remission and 19 partial remission. The complete remission was sustained at 42 months, although all but one of the patients with partial remission relapsed at a mean of 11 months.[123]

Transient Cold Agglutinin Disease

Transient cold agglutinin disease is a rare form that is always self-limited. Supportive measures, including transfusions and avoidance of cold, may suffice to tide the patient over the episode of hemolysis. Corticosteroids are usually not helpful, and splenectomy is almost never indicated.

PAROXYSMAL COLD HEMOGLOBINURIA

Clinical Features

Paroxysmal cold hemoglobinuria was historically associated with tertiary syphilis, which is rarely seen today. PCH is now more commonly seen primarily in children after a viral or, much less commonly, bacterial illness.[124] Most commonly, the viral etiology is not known but is associated with an upper respiratory tract infection. However, case reports in both adults and children have reported an association of PCH with varicella.

Although the Donath-Landsteiner antibody often occurs in tertiary or congenital syphilis, it generally does not cause hemolytic disease in this situation. On exposure to cold, an occasional patient experiences paroxysms of hemoglobinuria and constitutional symptoms (fever, back pain, leg pain, abdominal cramps, and rigors) followed by hemoglobinuria. In contrast, the postviral form of PCH[125–127] is characterized by constitutional symptoms with fulminant intravascular hemolysis and its associated signs of hemoglobinemia, hemoglobinuria, jaundice, severe anemia, and sometimes renal failure. The disease is self-limited, usually lasting 2 to 3 weeks, although it can be life threatening because of the severity of the hemolysis and consequent anemia.

Laboratory Evaluation

The IgG antibody responsible for PCH is found in the patient's serum through incubation of normal erythrocytes, fresh normal serum as a source of complement, and the patient's serum, first at 4°C and then at 37°C, with appropriate controls. The Donath-Landsteiner antibody fixes the first two components of complement in the cold and completes the cascade on warming to 37°C.[128] The DAT result is almost always negative, but occasionally weak reactions for erythrocyte-bound complement are manifested. The IAT result is negative. Most Donath-Landsteiner antibodies have specificity for the P blood group system,[129,130] but other specificities have been described.[131–133] The diagnosis depends on recognition of the clinical picture, because tests for the Donath-Landsteiner antibody are not routinely performed.

Therapy

No specific treatment for PCH has been found. Unlike the effectiveness of steroids in most IgG-mediated autoimmune diseases, prednisone is not useful for PCH. The best approach consists of supportive care, transfusions to alleviate symptoms, and avoidance of cold temperatures. The patient should be kept in a warm room, and transfusions should be given through a blood warmer.

DRUG-ASSOCIATED IMMUNE HEMOLYTIC ANEMIA

Drug-associated immune hemolytic anemia can be either induced by or dependent on a drug. Four distinct mechanisms are associated with the disorder. The first involves any drug that can bind to the RBC membrane. The patient then makes antibodies against the drug (e.g., penicillin), which combine with the erythrocyte-bound drug, opsonizing and preparing the RBC for destruction. Discontinuation of the drug brings the hemolytic anemia to a rapid halt, because the antibodies have no specificity for antigens on the RBC membrane. Clues to the diagnosis are the appropriate clinical setting, a positive DAT result, a negative IAT result, and failure of antibodies eluted from the patient's RBCs to bind to normal erythrocytes. The diagnosis is established when both the eluate and the patient's serum contain antibodies directed against the drug-coated cells. In the case of penicillin,[134] hemolytic anemia occurs only when large amounts are administered; in patients treated with lower doses, a positive DAT result without hemolytic anemia is not unusual, because the production of low-avidity IgG antipenicillin antibodies is a common event.

The second mechanism involves immune complexes. The offending drug, or drug metabolite, binds to a plasma protein, forming an immunogenic conjugate. If the patient develops an antibody to the conjugate, it is usually IgM. This antibody then binds to the immunogenic conjugate, forming an immune complex that adheres to RBCs. The resulting clinical

picture consists of intravascular hemolysis and concomitant hemoglobinemia, hemoglobinuria, and even renal failure through efficient activation of complement on the erythrocyte membrane. This chain of events accounts for most reported examples of drug-induced immune hemolytic anemia. Reports concerning the nonsteroidal drug diclofenac have shown that autoimmune hemolytic anemia is induced by sensitization to the glucuronide conjugate of the drug.[135] Serologic findings in erythrocyte-bound immune complexes are similar to those of the first mechanism, except that the DAT reveals only complement bound to the RBC; the IgM antibody is presumed to be no longer present after complement activation. The patient's serum reacts with RBCs (lacking antidrug antibody) in the presence of the offending drug, and the eluate from the patient's RBCs generally does not react with normal erythrocytes.

The third mechanism involves in vivo sensitization to drugs through the formation of immunogenic drug–RBC complexes. In these cases, the specificity of the drug-induced antibodies is contributed to not only by the drug (or its metabolites), but also by defined RBC antigens, particularly those of the Rh and I/i systems.[136]

The fourth mechanism of drug-associated immune hemolytic anemia involves the induction of authentic autoantibodies against RBCs by a drug; methyldopa is the classic example.[137] In as many as 20% of patients treated with methyldopa, the DAT result turns positive, but few demonstrate hemolytic anemia. The DAT result may take several months to a year or more after the start of drug therapy to become positive. In patients with hemolytic anemia, discontinuation of the drug results in only gradual cessation of the hemolytic anemia and disappearance of the autoantibody, because the drug itself is not required for the hemolytic process, only for the initiation of antibody production. Curiously, the autoantibody is usually specific for antigens of the Rh system. The serologic findings are indistinguishable from those in primary AIHA; they consist of a positive DAT result, usually a positive IAT result, and an eluate that reacts with normal erythrocytes. Patients taking methyldopa often have other antibodies in addition to the RBC autoantibodies. The mechanism by which methyldopa induces autoantibodies is unknown, but it may involve effects on immunoregulatory T cells.

Drug-induced immune hemolytic anemia was commonly seen when penicillin was administered in large doses (i.e., >20 million U/day) and when methyldopa was widely used in the treatment of hypertension.[138,139] However, the disease is unusual in present-day clinical practice.[140] Numerous drugs can induce hemolytic anemia.

ANIMAL MODELS OF AUTOIMMUNE HEMOLYTIC ANEMIA

Insights into Pathogenesis and Therapeutic Targets

NZB Mice

The inbred NZB mouse is genetically programmed to develop AIHA at around age 6 to 8 months (the life span of a normal mouse is approximately 2 years). Anti-erythrocyte autoantibodies begin to appear at around age 3 months; by age 9 months, the DAT result is positive in 60% to 80% of animals. Typical signs of hemolytic anemia develop—reticulocytosis, spherocytosis, a shortened RBC survival time, and splenomegaly.[141]

Okamoto and colleagues[142] developed a transgenic murine model of AIHA. The symptoms in this model range from unaffected to severe anemia. The B1 subpopulation has been demonstrated to mediate the AIHA.[143] They are activated in both T cell–dependent and T cell–independent ways.[144] These cells are unique from B2, the more prevalent B cells, in several ways. B1 cells preferentially locate in the peritoneal and pleural cavities, produce 50% of the natural serum IgM, and escape clonal deletion in these immunoprivileged sites. Interleukin-10 influences T cell–dependent proliferation of B1 cells and continuous administration of anti-interleukin-10 monoclonal antibody depletes B1 but not B2 cells in murine models. The influence of this Th2 cytokine on the behavior of the B1 cells in vivo[145] suggests possible avenues for treatments.

Origins of Anti-erythrocyte Autoantibodies

The vast improvement in our understanding of what prevents autoimmunization has not yet informed us of the mechanism that causes autoimmunization. Very little is known of the origins of warm-reactive IgG anti-erythrocyte autoantibodies, despite the availability of a thoroughly investigated, spontaneous animal model of the disease (the NZB mouse) and stocks of pathogenic autoantibodies, which are readily obtained from patients with the disease. A major impediment to advances in our understanding of how autoimmune hemolytic anemia originates is that the autoantigens are for the most part unknown. Even in those cases in which blood group specificity of the autoantibodies has been identified, the relevant structures have not been elucidated. Leddy and associates[146] have succeeded in identifying four proteins on the RBC membrane that bind to anti-erythrocyte autoantibodies; they are the band 3 anion transporter, glycophorin A, and two polypeptides, probably related to the Rh family of antigens. Various combinations of those four autoantibody specificities were found in a group of 20 patients with AIHA.

The association of AIHA with SLE and with immune thrombocytopenia (Evans's syndrome), the induction of the disease by drugs that seem to perturb immune regulation, and the graft-versus-host model of AIHA all suggest that, at least in some cases, there is antigen-independent activation of clones of B cells with the capacity to produce IgG anti-RBC autoantibodies. Such polyclonal B-cell activation may account for the production of anti-erythrocyte autoantibodies in patients with acquired immunodeficiency syndrome (AIDS).[94,147] Hypergammaglobulinemia and other signs of nonspecific activation of B cells are prominent in human immunodeficiency virus infection.[148]

The immunologic basis of AIHA in patients with CLL or a B-cell lymphoma is equally obscure.[149] In CLL, the autoantibodies are IgG and often polyclonal,[150] whereas the malignant CD5+ B cells of that disease generally produce only IgM antibodies that are monoclonal. It is therefore likely that B cells other than those constituting the leukemia produce the autoantibodies. The large mass of CD5+ B cells in CLL might induce nonneoplastic CD5− B cells to produce IgG autoantibodies, perhaps through a disturbance of immunoregulatory idiotypic networks. The demonstration of the simultaneous presence of autoantibodies and anti-idiotypic antibodies on RBCs in AIHA[151] suggests that such networks may indeed have a role in the disease.

In contrast to the antigens that incite warm-reactive autoantibodies, the structures of the autoantigens of cold agglutinin disease, the I/i system, are known[152]; this knowledge has clarified our thinking about the immunology of this group of disorders. There is little reason to doubt that the very high levels of monoclonal cold agglutinins found in some patients with B-cell neoplasms are produced by the malignant cells. The demonstration that an idiotypic marker on monoclonal cold agglutinins could be detected not only on the patients' neoplastic B cells, but also on 3% to 10% of normal B cells[153] supports the view that these autoantibodies are part of the normal immune repertoire; malignant transformation of a cold agglutinin–producing B cell results in a lymphoma complicated by chronic cold agglutinin disease.

The basis of the association of PCH with syphilis may be antigenic mimicry, in which structural similarities between a microbial antigen and a self-antigen trigger an autoantibody response. In the case of PCH, the infecting organism, *Treponema pallidum,* should possess two antigenic determinants (epitopes), one recognized by T cells (the foreign epitope) and the other by self-reactive B cells (the mimicking epitope). Donath-Landsteiner antibodies would be produced only by syphilitic patients whose class II major histocompatibility complex glycoproteins could present the foreign epitope in an immunogenic form to T cells. A similar mechanism could apply to postinfectious acute cold agglutinin disease, in which a crossreaction involving antigenic determinants of *M. pneumoniae* and the I blood group substance has been incriminated.[154]

Structural analyses of monoclonal anti-I and anti-i autoantibodies from patients with B-cell neoplasms are beginning to yield important clues about the origins of chronic cold agglutinin disease. A striking observation is the repetitive use of the same immunoglobulin V_H gene, $V_{H4\text{-}34}$, in monoclonal IgM cold agglutinins, regardless of the anti-I or anti-i specificity of the autoantibody.[155,156] In each case, the $V_{H4\text{-}34}$ heavy chain gene had a different CDR3 (complementarity-determining region 3); the light chains of cold agglutinins with anti-I or anti-i specificity differed as well. The $V_{H4\text{-}34}$ genes of these cold agglutinins contained few or no somatic mutations of the type that would lead to amino acid substitutions (replacement mutations). This finding, together with the variations in their CDR3 and in the light chains, implies that the $V_{H4\text{-}34}$ germline gene segment itself encodes a binding site for the I and i antigens. In contrast to the heavy chain gene, the light chain genes of the cold agglutinins do contain replacement mutations, especially in their hypervariable regions.[156]

It appears from these results that the germline $V_{H4\text{-}34}$ heavy chain encodes the dominant specificity of monoclonal cold agglutinins, the somatic mutations of the light chain genes of the cold agglutinins are the result of an immune response, and the V_H CDR3 and the light chain confer fine specificity (e.g., for I or i) on the cold agglutinin and influence its affinity. These data make a convincing case that monoclonal cold agglutinins arise as the result of an immune response, perhaps an autoimmune response to an autoantigen on erythrocytes. The results of these molecular studies of cold agglutinins complement other evidence favoring a role for antigen-mediated clonal selection in some types of B-cell neoplasms.

In contrast to monoclonal cold agglutinins associated with chronic cold agglutinin disease, the naturally occurring IgM cold agglutinins that are present in low titers in normal serum are not restricted to the $V_{H4\text{-}34}$ gene segment. They are associated with different genes of the V_{H3} family as well as the $V_{H4\text{-}34}$ gene.[156] It therefore appears that B-cell neoplasia is an important but not exclusive element in the association between $V_{H4\text{-}34}$ and cold agglutinins. The correlation with lymphomas has additional interest, because $V_{H4\text{-}34}$ has been independently linked to B-cell lymphomas that do not secrete cold agglutinins.[157]

PERSPECTIVE

In previous years, there have been many debates concerning the factors that contribute to the severity of AIHA. Previous studies have focused to a large extent on the humoral aspect of the autoimmune response. The antibodies were easily available from peripheral blood, allowing for many serologic investigations. However, none of the serologic parameters by itself—the quantity of serum RBC autoantibodies, titer, thermal amplitude, or allotype—has proved useful in predicting severity of the disease in patients. This fact is perhaps not surprising, because RBC clearance in both cold and warm AIHA occurs predominantly extravascularly through the actions of macrophages rather than intravascularly through antibody-mediated complement lysis. Also, membrane receptors on macrophages, such as FcγIIRB and SIRPα (signal regulation protein-α), have been identified that have the ability to modulate RBC clearance and, thus, severity of hemolysis. Therefore, it is possible that the activity of these receptors may vary among patients as well, contributing to the severity of disease expression. Moreover, these macrophage receptors may prove to be viable targets for the development of more specific immunotherapy than the methods currently used (i.e., corticosteroid therapy and IVIG). Another potentially exciting therapeutic approach is targeting of the humoral immune response, either through direct targeting of the B cells, such as with anti-CD20 antibody, or through interference with the interactions between B and T lymphocytes, such as with costimulatory molecule blockade (e.g., anti-CD40 antibody).

Chapter 42

Transfusion in Economically Restricted and Developing Countries

Audrey N. Schuetz • Kenneth A. Clark

Until the human immunodeficiency virus (HIV) pandemic in the 1980s, transfusion services in many economically restricted countries remained poorly developed, primarily due to economic constraints. With the institution of HIV testing in 1985 in the United States and in other developed countries, economically restricted countries were encouraged to place a stronger focus on transfusion safety practices. Although transfusion safety has improved somewhat over the past few decades, many economically restricted countries continue to struggle with inadequate resources and infrastructure that hinder establishment of a safer blood supply. According to the World Health Organization (WHO), only 20% of the worldwide supply of safe and screened blood is available to people living in economically restricted countries, where approximately 80% of the world's population resides.[1,2]

Enforcement of a successful transfusion service depends on several levels of commitment, from the government administration to the staff delivering the blood. Optimally, blood transfusion services consist of education, recruitment and adequate selection of safe blood donors; collection, processing, and storage of blood products; performance of serologic and other tests on the products before transfusion at the collection facility; and, finally, transportation and subsequent release of the blood to patients with appropriate need for transfusion.

Commitment of governments to a well-developed and organized blood transfusion service is the first key to sustainable and successful blood transfusion systems. Many economically restricted countries are faced with a high disease burden but lack the infrastructure to address the problem. Various organizational structures of blood services are described in this chapter, as is the commitment of the WHO to worldwide blood safety.

A second key to optimizing blood transfusion services includes selection of safe blood donors by recruitment of nonremunerated (*nonpaid or voluntary*) individuals. In the developed world, donor screening focuses on excluding individuals who carry a higher "risk" of infectious disease than the general population; such individuals include intravenous drug users, men who have sex with men, and commercial sex workers. In economically restricted countries, such as Africa, where heterosexual transmission has accounted for as much as 80% of all HIV infections, such focused donor screening is less effective.[3,4] A strategy employed by economically restricted countries to select safe blood donors involves predonation laboratory testing of blood with rapid diagnostic tests.

In the third place, proper laboratory testing of donated blood and adequate record keeping present challenges to blood centers with financial and logistical restrictions. Testing and storage of blood is limited by the lack of reliable sources of electricity and refrigeration, as well as by the cost of machinery, reagents, and testing kits.

Finally, transfusion safety relies on appropriate blood administration to recipients. Given the difficulties in donor screening and laboratory testing of blood, consideration must be given to balancing the risk of exposure to a transfusion-transmitted infection versus the risk of no transfusion. Furthermore, because children comprise the largest proportion of transfusion recipients in certain regions and pregnancy- or malaria-associated anemia also rank among the highest indications for transfusion in many economically restricted countries, the morbidity and mortality associated with a transfusion-transmitted infection may be potentially high among certain populations.

Although two decades have passed since relatively simple HIV tests became available to screen blood donors and products, the lack of economic and political resources has compromised the blood supply in many areas of the world. The overwhelming challenges are evident when faced with the fact that approximately 10% of all acquired immunodeficiency syndrome (AIDS) cases in certain areas of the world are transfusion associated.[5,6] However, improvements have already begun; Zimbabwe was the third country in the world to routinely test donated blood for HIV.[7] Various organizations are currently gathering data on methods to improve governmental infrastructure, to understand disease epidemiology, and to adjust current transfusion practices and attitudes toward blood safety in economically restricted countries.

GOVERNMENTAL ORGANIZATION OF BLOOD SERVICES

Development and organization of blood transfusion services in economically restricted countries has not only lagged behind blood services in developed countries but has also lagged behind other parts of the health care system as well.[8] The sustainability of high-quality transfusion systems in economically restricted countries is best achieved with national oversight and a national commitment to safe blood transfusion as part of the health care system. The WHO claims that a well-organized blood transfusion service is a prerequisite

Table 42–1 Key Organizational Elements of a National Blood Transfusion Service

Formalization of government commitment and support
Establishment of a national blood policy or plan
Establishment of legal authority through legal or regulatory framework
Establishment of a responsible organization to oversee and implement the national blood transfusion service
Appointment of a national blood service medical director, a quality manager, and appropriate advisory groups
Development of financial and budgetary systems to ensure sustainability of the national transfusion service
Establishment of a national quality system[9]

for the safe and effective use of blood products while emphasizing government commitment as a strategic priority.[9,10] The WHO also recommends that governments establish blood transfusion services as a separate entity with an adequate budget, effective management, and trained staff.[9,11]

The key organizational elements of a national blood transfusion service in an economically restricted country, as suggested by the WHO, are listed in Table 42–1. Organization of blood services varies considerably throughout the world with regard to geographic regions and availability of resources. The organizational structure of blood services is outlined in Table 42–2.

Several types of organizational blood banking structures operate worldwide. Hospital-based systems predominate in economically restricted countries; centralized or regionalized blood transfusion systems operate largely in developed countries.[12,14,15] In sub-Saharan Africa, where blood services are predominantly hospital-based, blood transfusion systems are moving toward a more centralized or regionalized approach in countries such as South Africa, Uganda, Kenya, Zimbabwe, and Togo.[16] In addition, some northern African countries bordering the Mediterranean Sea have made considerable progress toward centralization. Centralized blood collection systems are more advantageous than small hospital-based systems, because they have a greater number of highly trained specialists with the ability to handle a larger number of blood units.[17] In contrast, blood programs in economically restricted areas of South and Central America are largely decentralized, some to a high degree. For example, Argentina has more than 1000 blood banks.[18–20] A similar situation exists in economically restricted areas of Southeast Asia, where there is extensive decentralization of the blood system.[18]

Blood services in economically restricted countries, just as in more developed countries, should be defined by a legal framework that states the national blood policy and describes the processes governing the collection, processing, and transfusion of blood.[21–23] A variety of organizations collect and process the blood in economically restricted countries, typically including the ministries of health, social security systems, the armed forces, private organizations, and nongovernmental organizations. Blood transfusion services, which oversee the delivery of blood products to patients, are usually operated by health care facilities, such as hospitals.[19]

The WHO recommends that governments of economically restricted countries take responsibility to ensure a safe and adequate blood supply. Indicating the need for national support of blood transfusion programs, the 58th World Health Assembly (WHA) passed resolution WHA58.13 in May 2005, urging member states to support full implementation of well-organized, nationally coordinated, and sustainable blood programs with appropriate regulatory systems.[24] In particular, the resolution advocated government commitment and support for national blood programs with quality management systems, by means of a legal framework and a national blood safety policy and plan. Many economically restricted countries have made significant organizational advances in the past decade, but improvements are still required.

BLOOD DONOR RECRUITMENT, SELECTION, AND SCREENING

In 1975, the WHA adopted Resolution WHA28.72, which required its members to promote the development of national transfusion services based on the use of voluntary, nonpaid blood donors.[2,25] Replacement donors are recruited from among the family or relatives of hospitalized patients who require blood transfusions. A number of studies have shown that voluntary donors often have a lower prevalence and incidence of infectious transfusion-transmitted diseases than do family/replacement donors and paid donors.[17,26–33] In Kenya, a study comparing volunteer donors from mobile blood units with donors recruited by family members showed that HIV seroprevalence among voluntary donors was significantly lower than among family-recruited donors (1.7% and 9.1%, respectively; odds ratio, 5.9).[34] Information collected in the Global Database on Blood Safety has repeatedly shown the importance of recruiting voluntary blood donors.[35]

Blood centers in sub-Saharan Africa routinely rely on family/replacement or paid donors for a significant percentage of their blood collection needs, often due to shortages in supply of donor blood in the blood banks. A lack of resources to train personnel and to provide transport for mobile blood campaigns contributes to blood shortages as well. From 50% to 70% of donations are collected from family/replacement and paid donors worldwide, often in countries with relatively high prevalence of HIV, hepatitis B virus (HBV),

Table 42–2 Organizational Structure of Blood Services

Centralized	One national blood center operates the blood services for the country, with or without regional blood centers.
Regionalized	The country is divided into regions of varying degrees of autonomy, with different mechanisms to achieve national coordination.
Hospital-based	Each hospital operates its own blood collection and processing system, with or without national control.
Combination of above	There may be a national blood transfusion system, but hospitals may find the national coverage unsatisfactory and choose to operate their own systems.[12,13]

and hepatitis C virus (HCV) infection.[25,36,37] A blood bank in Armenia reported that 12% of the 1010 units of whole blood collected in 2004 were drawn from paid donors, and 88% were drawn from patient relatives (JB Gorlin, personal communication, November 17, 2005).

Although the WHA resolution has not been fully adopted in many economically restricted countries despite its implementation more than a quarter-century ago, progress has been made. By the year 2000, 39 of the 192 WHA member states had achieved 100% voluntary, nonremunerated blood donation.[24] Approximately 40% of the 30.2 million blood donations performed in 1999 in economically restricted countries were obtained from low-risk voluntary donors. One of the blood banks in Armenia has, for the first time, organized blood drives and collected 172 units of blood from volunteer donors, including medical students (JB Gorlin, personal communication, November 17, 2005).

To emphasize these problems, the WHA reiterated the call for encouraging voluntary blood donations in resolution WHA58.13.[24] Some countries have reported that elimination of paid donors has paralleled a decline in the seroprevalence of HIV in individuals who present for blood donation.[20,38–40] Although recruitment of voluntary blood donors is costly and difficult, marketing strategies aimed at increasing the proportion of repeat voluntary donors have met success in countries such as Venezuela, Nicaragua, and Cuba.[41,42]

Donor Selection

Despite inherent difficulties in selecting donors in areas of high prevalence of infectious diseases, donor recruiters in economically restricted countries have attempted to identify effective risk factor deferral criteria using medical history, demographic information, and social history.[43–54] In sub-Saharan Africa, age has been used as a surrogate marker for infectious risk. Although the age for peak seroprevalence of HIV varies in different regions in sub-Saharan Africa, peak seroprevalence of HIV is typically age 15 to 29 in women and age 25 to 39 in men.[55] Therefore, recruitment of donors has shifted to secondary school students and older adults in such areas of the world.

Another potential surrogate marker for donor infectious risk is demographic status. In general, HIV prevalence is lower in rural populations than in urban centers.[56] However, recruitment of rural donors can be difficult and is more expensive due to limited transportation infrastructure and potentially lower levels of nutritional health, which result in higher rates of anemia.[30]

One study reported that blood donor self-deferral can reduce the risk of HIV transmission through blood transfusion.[57] Self-deferred donors demonstrated significantly higher rates of HIV, HBV, and HCV as compared to general donors.

In an effort to circumvent the problem of identifying a suitable low-risk donor population by risk-deferral screening, donor recruitment activity often focuses on secondary schools, selected businesses, churches, and repeat-donor clubs. For example, in Zimbabwe, attempts have been made to collect blood only from individuals with a recent prior blood donation history and to establish repeat-donor groups.[37]

Because funding and resources for mobile donor recruitment are limited, blood centers are often forced to rely on family/replacement donors to fill the available blood deficit.

Predonation Testing

Worldwide, prospective blood donors are screened for transfusion-transmissible diseases. In addition, adequate hematocrit should also be assessed. The high prevalence of anemia often contributes to a dearth of eligible blood donors, such as at a transfusion center in Nigeria, where 75% of donors were rejected for anemia alone.[58]

In certain countries, blood services and hospitals test donors for HIV and other infectious disease markers by rapid test methods before donation. Proponents of predonation testing argue that the advantages of pretesting in areas of high prevalence of HIV, HBV, and HCV, such as in sub-Saharan Africa, outweigh the disadvantages. Advantages of pretesting include:

1. Savings on the cost of blood collection bags and waste disposal
2. Savings on the cost of the equipment and supplies needed for postdonation enzyme immunoassay testing
3. Fewer units of stored blood to include only screen-negative units
4. The ability to quickly inform deferred donors of their test results in regions where mail and telephone communication is poor and the likelihood of repeat donation is low[59,60]

Collection centers in populations with high infectious disease prevalence may find predonation testing strategies attractive from a cost- and resource-savings perspective.

High prevalence of infectious diseases in donors not only compounds the risk to the recipient, but also increases the overall cost of the transfusion product. Because blood collection bags represent as much as one third of the blood bank budget, money is wasted on bags thrown away due to infected donors.[35] Rates of donor deferral after laboratory screening, based on a positive infectious disease result in the donor, may exceed 10%. Positive HBV surface antigen (HBsAg) tests on donor units accounted for more than half of the discarded units in one Ghanaian study.[60] The decrease in cost associated with predonation screening may be significant when transfusion-transmitted infection prevalence among donors reaches 15% to 20%.[59] Well-organized blood safety programs that depend mainly on voluntary, nonremunerated blood donors should expect discard rates of less than 10%, even in areas with high infectious disease prevalence.

Even though prescreening donor units may be economical, it poses a challenge when used to prescreen for HIV or hepatitis, particularly in sub-Saharan Africa.[61–63] Most often performed in blood collection sites in small rural hospitals and clinics, predonation testing may be troublesome due to the lack of qualified staff, organized recruitment system for volunteer donors, or quality management system. In many countries, low-skilled technicians may perform donor prescreening with rapid tests and may not have the skills to perform more complex tests for follow-up or to guarantee that the other basic operations and functions of a proper transfusion service are carried out.[59] Counseling and physician referral of positive donors may not routinely take place; when performed, counseling may be inadequate due to insufficiently trained staff.

Caution must be exercised while practicing predonation testing, because blood transfusion centers have the potential to become test sites for persons who simply wish to know their HIV status.[64] Voluntary counseling and testing (VCT)

centers in many economically restricted countries with high HIV prevalence enable persons to discover their HIV status and provide them with counseling and prevention advice. Blood centers that prescreen donors may themselves be at risk of becoming alternative VCT centers. Some persons may choose to be tested at blood transfusion centers, rather than at VCT centers, due to a lower perceived stigma in visiting a blood collection center. Blood centers that prescreen donors may attract persons who primarily wish to know their HIV status and, by inference, have high-risk behaviors. If an error occurs in the testing procedures and an infected person is overlooked, blood donations from such individuals could compromise the safety of the blood supply. For this reason, efforts should be made to separate the process of blood donation from determination of infection status.

Another disadvantage of the predonation testing process is the disqualification of many donors at the donation site. In areas of high HIV prevalence, the public may be suspicious that any deferral is due to a positive HIV test result. Therefore, the donor or public may consider any deferral, even for a low hemoglobin value, as synonymous with HIV positivity. The stigma attached to this label is well known and significant.[59]

Most importantly, adoption of the practice of predonation testing by itself does not address the larger obligation of blood centers to establish a reliable donor recruitment system. Because clinicians may transfuse blood from prescreened donors very soon after collection, sometimes without the support of additional postdonation testing, a safe pool of volunteer donors is important. In many economically restricted countries, few organized blood donor recruitment systems with networks of repeat donors exist.

Rather than accepting high-risk donors as the norm, an organized blood donation system should attempt to develop strong programs of donor recruitment and selection, with strong quality management. The optimal blood donation practice would only allow blood collection facilities with a sufficient scale of operation and with sufficient numbers of qualified staff to properly collect blood from a network of low-risk blood donors. The development of a pool of safe and reliable donors should be a primary goal for blood transfusion safety programs in economically restricted countries.

INFECTIOUS DISEASE TESTING OF BLOOD

In the practice of transfusion safety, laboratory testing of donated blood provides the link between choice of a suitable blood donor and appropriate transfusion to the recipient. Regional epidemiologic data guide the choice of infectious disease testing. Globally, the major mode of HIV transmission is sexual, and HIV tests have become the cornerstone of testing in many economically restricted countries. HIV, HCV, and HBV are 10 to 100 times more prevalent in Tanzania, for example, than in many developed countries.[65] Blood banks in Latin America screen for the parasite *Trypanosoma cruzi*, the etiologic agent of Chagas disease, which infects an estimated 18 to 24 million people in Latin America.[66]

The choice of screening assays by the blood bank or laboratory depends not only on the region's infectious disease epidemiology, but also on the quality and types of assays available. Financial and logistical limitations may also limit the choice of an assay. A detailed description of infectious disease blood screening assays is offered elsewhere in this textbook (see Chapters 14 and 43–48). Here we present an overview of some screening methods practiced in economically restricted countries.

Rates of Infectious Disease Screening

Despite differences in disease epidemiology and financial resources between countries, the WHO strategy for laboratory screening of blood recommends HIV, HBV, and syphilis screening of all donated blood and, when appropriate, screening for HCV, malaria, and Chagas disease.[25] Yet, according to the WHO's Global Database on Blood Safety, less than 60% of economically restricted countries screen all their blood for HIV and even fewer countries screen for HBV or HCV.[25] Among the 75 million donations per year worldwide, 30 million are collected in economically restricted countries, where only 43% of the blood supply is screened for HIV, HBV, HCV, syphilis, and Chagas disease.[67] Based on those figures, approximately 12.9 million donations (17% of annual blood donations worldwide) are potentially infectious for HIV, HBV, HCV, syphilis, and/or *T. cruzi*. The WHO estimates that in 2002, 90% of blood donations in Africa were screened for HIV, whereas only 40% were screened for HCV.[68] In sub-Saharan Africa, only one half of the blood supply is currently screened for HBV.[69] Brazilian blood banks report low rates of screening for HTLV and HBV core antibody, ranging from 17% to 60%.[70,71]

Although the WHO standard has not yet been reached, much progress has been made. By 1998, the number of blood donors in Uruguay with Chagas disease was negligible, in part due to 100% compulsory blood screening.[72] Reports of blood donor screening in Latin America show that greater than 95% of the blood units are tested for HIV, HCV, and HBV; Costa Rica, Mexico, and Panama report the lowest numbers of units screened for *T. cruzi*.[20,22,38,73] However, some Latin American countries, such as Colombia and some areas of Argentina, report low rates of screening.[74,75] According to the Pan American Health Organization (PAHO), the countries of Latin America and the Caribbean collected approximately 6 million units of blood in 1999, of which approximately 99% underwent screening for HIV and HBV and 94% for HCV.[38] In 2001, despite an increase of 14% in the number of units collected as compared to 1999, greater than 99.9% screening coverage for HIV, HBV, and HCV continued in Latin America and the Caribbean.[38] A 1994 study in India claimed that only 25% to 75% of blood donations were being screened for HIV.[76] However, by 2000, a nationwide study of 604 blood banks in India reported 95% screening coverage for HIV, 94% for syphilis, 87% for HBV, 67% for malaria, and 6% for HCV.[77] Accurate data on rates of blood bank screening are difficult to obtain and vary according to region but are nonetheless important in assessing safety of donated blood.

Infectious Disease Screening Tests

In general, screening tests for HIV antibodies, HBsAg, and HCV are performed with enzyme immunoassay (EIA) test kits. Polymerase chain reaction testing and HIV p24 antigen testing are usually not affordable, nor are they logistically appropriate for use in most economically restricted countries.

Although most countries screen their blood supply for antibodies to HIV-1 and HIV-2, some regions are exploring other diagnostic methods. Rapid HIV testing may be

an adjunct to predonation screening or a field alternative to technical laboratory testing. The HIVCHEK rapid test, an instrument-free, single-unit system that can be stored at ambient temperature, was judged suitable for use in underequipped transfusion centers when tested in the Democratic Republic of Congo.[61] Nucleic acid amplification testing (NAT), which effectively identifies infectious donations in the preseroconversion window period, was compared to the traditional HIV antibody test and the p24 antigen test in South Africa, an area where HIV-1 infection is endemic.[78] In the South Africa study, researchers found that implementation of NAT in addition to HIV antibody screening allowed discovery of only an additional 17 to 23 HIV-positive donations per year if p24 antigen testing were eliminated from the screening regimen. The cost-benefit ratio of introducing an expensive technology, such as NAT, in an economically restricted country merits further assessment.

The high HIV prevalence in the general population in some economically restricted countries increases the probability of false-negative tests. Although the EIA tests most commonly used for antibody screening are highly sensitive, window period donation incurs residual risks of infection. Researchers estimate that the rate of transfusion-associated transmission of HIV due to window period donation in South Africa ranges from 1:25,641 to 1:90,909 tested units, which is 10 times greater than the rate of laboratory false negatives.[78] Two of the three probable transfusion-transmitted HIV cases that were reported to the hemovigilance program in 2003 in South Africa occurred during the window period of infectivity.[79]

Some countries across the globe have reported an increase in the prevalence of infectious disease markers, which could be due in part to an improvement in the sensitivity of screening markers. In Thailand, the prevalence of HIV in the supply of donated blood rose from 0.0065% in 1987 to 0.95% in 1993.[80] A review of blood donor screening results in India from 1996 to 2001 showed an increase in the prevalence of HIV from 0.16% in 1996 to 0.3% in 2002.[81]

See Table 42–3 for prevalence data on infectious disease markers in selected studies. The prevalence of serologic markers for HIV, HBV, HCV, and *T. cruzi* in many Latin American countries was extensively reviewed by the PAHO.[20] Refer to the PAHO article by Schmunis and Cruz for a complete review of seroprevalence rates among blood donors in Latin America.

Hepatitis C virus presents a significant public health problem, with major associated morbidity and mortality in both developed and economically restricted areas of the world. In Korea, where mortality due to liver cancer ranks high worldwide, the prevalence of anti-HCV among Koreans older than age 40 was 1.29%, with blood transfusion as the strongest risk factor for transmission of HCV.[102]

Investigators from a major hospital in Ghana, where the prevalence of HBV in blood donors was 8% to 15%, compared three HBV screening assays (HBsAg latex agglutination, HBsAg dipstick, and HBsAg enzyme immunoassay) in blood donors.[69] The latex agglutination and dipstick assays, which are used in Africa due to their low cost and flexibility, had low sensitivities of 54% and 71%, respectively, but they continue to be used in many areas of the world.

§ JB Gorlin, personal communication, November 17, 2005.

In contrast to developed countries, economically restricted countries continue to rely on syphilis testing as a means of disease screening. Both the reagin tests, such as the Venereal Disease Research Laboratory (VDRL) test, and the treponemal tests, such as the *Treponema pallidum* hemagglutination assay (TPHA-FTA ABS), detect syphilis antibodies. Some countries with a low prevalence of syphilis use TPHA-FTA ABS, because its sensitivity and specificity are higher than those of the reagin tests.[103,104] Yet, the TPHA-FTA ABS costs more and is more complex than the reagin tests. In countries with high syphilis prevalence, the VDRL test may be more appropriate in diagnosing the infectious phase of syphilis. In Thailand, at a clinic for laborers, HIV-1 seropositivity correlated positively with positive TPHA-FTA ABS results, with an odds ratio of 1.8 ($p = 0.015$).[105] Such findings support the continued use of syphilis screening as both a marker for other diseases and as a means of disease diagnosis in economically restricted countries.

Antibody testing for HTLV-I, the etiologic agent of adult T-cell leukemia, is generally not performed in economically restricted countries. HTLV-I is endemic in southwest Japan, the Caribbean, Central and South America, sub-Saharan Africa, Papua New Guinea, Australia, the Solomon Islands, and western Asia but is not a required test in many of these regions.[106,107]

Screening for Chagas disease in endemic areas of Latin America is performed using EIA methods to detect *T. cruzi* antibodies. The main serologic methods for identification of *T. cruzi* antibodies are the indirect hemagglutination assay, the indirect immunofluorescence assay, and the enzyme-linked immunosorbent assay (ELISA). The indirect hemagglutination assay, although easy to perform and widely used, is the least sensitive of the three tests.[108,109] Blood centers in Brazil most often use the ELISA, according to a series of external quality control assessments of blood bank laboratories performed in 1999 and 2000.[108] The use of two different screening methods, most often the combination of an ELISA test and an indirect hemagglutination test, minimizes the risk of false negatives.[108,110] The indirect immunofluorescence assay is less commonly used.

Although recommended in malaria-endemic areas, malaria screening in very high prevalence areas, such as sub-Saharan Africa, is neither practical nor effective, because the majority of donors and recipients would test positive. In areas of low malaria prevalence, such as Southeast Asia, malaria screening with Geimsa-stained blood films is common but not universal.

Cytomegalovirus (CMV) antibody testing also is not routinely performed in the economically restricted world, and very few studies are available on its use. In a recent study in India, none of the 200 voluntary blood donors in Delhi tested positive for CMV immunoglobulin M (IgM) antibody, but 95% were positive for CMV IgG antibody.[111] Testing of donors would be superfluous, because very few seronegative blood units would be available for transfusion.

Very few studies on human herpes virus-8 (HHV-8) have been performed in economically restricted countries. HHV-8 antibodies among 306 blood donors in South Africa were present in 2% to 10% of individuals, with increasing prevalence with age.[112] Because the seropositivity for HHV-8 was relatively high in these blood donors, screening for this herpesvirus may be useful, given the association between HHV-8 and Kaposi sarcoma.

Finally, although hundreds of cases of human infection with *Babesia* spp. have been reported in the United States, only a few cases have been described in China, Egypt, Mexico, South Africa, and Taiwan, currently indicating a low need for *Babesia* screening in economically restricted countries.[113]

Other potential laboratory surrogate markers for infectious disease risk have been examined in economically restricted countries, such as serum alanine aminotransferase (ALT) levels, yet they have met with limited success. Studies of serum ALT in Indian blood donors have shown no correlation with viral seropositivity of HBV, HCV, HIV, or CMV.[114]

Transfusion-Associated Infectious Risks

Transfusion-transmitted infections are among the largest risks of receiving a blood transfusion in economically restricted countries. Among the infectious diseases, HIV has one of the most serious adverse consequences. In contrast to data from the United States, where significantly less than 1% of HIV infections are estimated to be transfusion transmitted, data from economically restricted countries show that 5% to 10% of new and existing HIV infections are due to blood transfusion.[31,115–117]

Although estimates on transfusion-transmitted HIV proved difficult to gather during the early stages of the AIDS epidemic, as many as 25% of HIV-infected children and women in Africa are believed to have acquired HIV from blood transfusions.[118–120] McFarland and colleagues estimate that in sub-Saharan Africa alone, 25% of pediatric AIDS cases, 20% of adult female AIDS cases, and 10% of all other AIDS cases may be associated with transfusion.[121] Blood transfusions in sub-Saharan Africa rank third among modes of HIV transmission, most notably affecting children under age 5.[122,123] In the Caribbean, 1.1% of AIDS cases are due to blood transfusion.[124] In Brazilian blood donors, a history of blood transfusion is thought to be the etiology in 15% of HCV-positive cases.[125] Transfusion before 1992 is considered to be the major route of transmission for HCV in Japan.[126]

The risk of receiving HIV-positive blood in Africa ranges from less than 1% to more than 20% per unit of blood, depending on the country studied.[6] In a 2001 survey of 1482 blood units in six government hospitals in Kenya, 31 (~2%) units tested HIV-positive on follow-up at the reference laboratory, of which 14 had tested negative by the hospital and were not removed from the blood supply.[34] HIV test results for 1290 donor–recipient pairs showed that 26 of the 31 HIV-positive donations had been given to individuals who were HIV-negative before transfusion. As a result, the estimated HIV transmission rate was 2% in these hospitals. In 1985 in Kinshasa, Democratic Republic of Congo, 561 HIV-positive blood units were transfused to children in one pediatric hospital ward.[127]

Studies continue to show unacceptably high rates of HIV transmission from blood transfusion. In a pediatric tertiary care center in India, 33 of the 285 HIV-positive children were infected through blood transfusion from 1994 to 2001.[128] A study in rural China in a region with a large percentage of paid donors showed that 1% of the 115 HIV-positive residents obtained infection through blood transfusion.[129] Finally, in a consecutive survey of 222 women at prenatal and pediatric clinics who had received transfusions between 1980 and 1985 in Kigali, Rwanda, HIV seroprevalence was

45%, compared to 28% in nontransfused women presenting to the clinics.[130]

The probability of seroconversion from transfusion with a single HIV-positive unit of blood is 90%.[131] The risk of HIV from a screened unit of blood in Ivory Coast in 1992 was two to three times greater than the risk of acquiring HIV from a seropositive needlestick exposure.[132,133] Approximately 142 to 276 units of potentially infected blood units were transfused annually in the early 1990s in the Ivory Coast, despite routine testing.

Paid plasma donors are becoming an increasingly recognized reservoir of infection in the blood bank community. Paid donors typically become infected at plasmapheresis centers through unsafe practices, such as the use of nonsterile needles, sharing of intravenous lines, and injection of donors with blood to hyperimmunize them for anti-Rh_o and serum typing production.[134,135] Unlicensed plasmapheresis centers began appearing in the 1990s in China, where poor peasants in communities with few risk factors for HIV began selling their plasma at unsanitary centers and became subsequently infected.[90,136] Some of these centers directly contributed to spread of disease in donors through the pooling of blood from donors of the same ABO type before returning the red cells to each donor. High rates of HIV seropositivity have been discovered among repeat blood donors, especially paid donors.[137,138] At one illegal plasma collection site discovered in central China between 1998 and 1999, 71 of the 96 paid donors were positive for HIV.[139] At another site, 50% and 100% of all donors tested positive for syphilis and HCV, respectively, and the entire group of 142 tested samples were positive for HIV.[90]

Multifaceted approaches to curb the use of unscreened or unsafe blood are needed. In response to the high use of unscreened blood for transfusion in Nigeria, the government instituted a law to regulate blood transfusions by requiring blood banks to register their blood donors, with fines and imprisonment for offenders.[140]

Hemovigilance data systems throughout the world are incomplete, particularly in economically restricted countries. More data on infectious disease prevalence are needed to assess effectiveness of screening procedures and guide further laboratory testing.

Logistics and Finances of Laboratory Screening

Although basic compatibility testing is performed in economically restricted countries, many blood banks run only ABO grouping and Rh typing in lieu of crossmatching. More extensive testing, such as additional alloantibody or autoantibody identification, extends beyond the current capabilities of blood banks in economically restricted countries due to limited technical expertise and a lack of automation, reagents, and adequate training.

Logistical problems often challenge laboratories in economically restricted countries. Laboratories may lack a standardized reporting system for results or have poor record keeping. Educational systems for blood bank personnel are also lacking. The cold chain for laboratory support may be compromised, with lack of a standard refrigerator, often with inadequate storage space for blood components. One researcher emphasizes the logistical problems by pointing out that:

> [a]lthough Tanzania's health policy is that all blood should be screened anonymously for infections which can be transmitted on transfusion, health experts say that a lack of systematic and comprehensive blood-screening support programme has undermined this goal. There is no screening for other infections, because the health ministry does not routinely supply test kits to hospitals due to financial constraints.[45]

Small blood banks may exist as unregulated commercial operations without quality control.[141]

Innovative answers to logistical problems in economically restricted countries are needed. One such example is the development of the slide Polybrene method for pretransfusion compatibility testing, in response to the lack of centrifuges in some areas.[142] Simple to use, the slide Polybrene can be performed by personnel with minimal training.

During an attempt to simulate suboptimal storage conditions in economically restricted countries, researchers tested blood units for HIV with inappropriately stored or expired rapid antibody assays in Zambia.[143] The sensitivity and specificity of the tests were 11% to 18% lower than the manufacturer's claim, with a risk of contracting HIV through transfusion at least six times higher than expected.

Blood screening for infectious diseases proves cost effective, especially in areas with large numbers of HIV-positive individuals.[27,61,144] Supplies and equipment comprise the majority of cost in blood transfusion.[145] To prevent one case of HIV in Africa, measures to improve blood transfusion safety may cost from $US 20 to $US 1000.[146] One study reported that savings exceeded costs by a factor of 2.7 to 3.5 in a region of Zambia with an HIV seroprevalence among donors of 16%.[87] A Tanzanian study showed that safe transfusion practices can be assured at an annual cost of $US 0.07 per capita.[147] One method of recovering the cost of screening blood involves charging all inpatients a fee that covers the screening costs on admission.[13] Charging all patients rather than only those patients who received blood by transfusion is easier to institute and does not lay the cost burden on the women and children who require the majority of transfusions.

Poor funding and lack of government support also lead to suboptimal practices. In a survey of 62 hospitals in the Democratic Republic of Congo in 1991, only 29% regularly received HIV testing kits due to lack of funding.[148] As a result, 28% of the blood units transfused during the study period were not screened for HIV. Logistic and economic issues should be better understood to assess the feasibility of laboratory testing in economically restricted countries.

BLOOD USAGE

Clinicians must weigh several factors when administering blood products, including the recipient's underlying need for transfusion, infectious contamination risks, and other noninfectious risks of transfusion. Despite the considerations that should be made in deciding to transfuse, blood transfusions continue to be performed unnecessarily in some instances.

Transfusion Recipient Populations

Transfusion recipient populations in economically restricted countries differ from those in more industrialized countries. Blood recipients in developed countries generally include cancer or transplant patients, adults undergoing surgery, and

hemophiliacs. In economically restricted countries, recipients typically include children, pregnant women, sickle cell disease patients, victims of trauma, and persons with hemoglobinopathies, severe parasitic infections, and nutritional anemia.

In many areas of the world, children comprise a large percentage of those receiving transfusions. Between 19% and 67% of hospitalized children in Africa receive transfusions.[67,118,119,127,149,150] In Uganda, 65% of all transfusions are performed on children under age 5, the majority of whom suffer from malaria and other infections, malnutrition, and sickle cell disease.[151] Often, the youngest children require the majority of transfusions, due in part to the length of time required for children to develop immunity to certain pathogens, specifically malaria. A study conducted among six government hospitals in Kenya found that 58% of transfusions were requested for children age 10 or younger, and 37% for children under age 2.[34] Pediatric transfusions were primarily administered for malaria (49%), but were also administered for surgery (14%) and chronic anemia (11%). Finally, a retrospective study of blood usage in Mozambique showed that the pediatric department ordered nearly half of the blood used for transfusion, primarily for management of anemia.[152]

A second population group that receives a large proportion of transfusions in economically restricted countries is pregnant women. In sub-Saharan Africa, pregnant women often suffer from anemia due to malaria, iron and folate deficiency, or sickle cell trait or disease, which may be compounded by malnutrition or other health problems such as hookworm infestation.[153] Tanzanian studies show that pregnant women receive 8% to 11% of all transfusions.[154,155]

Patients with sickle cell disease are another large population sector requiring multiple transfusions. Most of the world's population with sickle cell disease resides in Africa, with the remainder in the Middle East or India.[156,157] Other areas of the world have reported significant numbers of sickle cell disease as well. Since implementation of neonatal sickle cell screening in 2000, one case of sickle cell disease per 1196 births in Brazil has been diagnosed.[158] Insufficient transfusion facilities unfortunately hinder the application of long-term transfusion protocols for these patients.

Finally, thalassemia patients comprise another major population group that receives a large proportion of blood transfusions in economically restricted countries. Thalassemia is an important public health problem in Southeast Asia, Africa, India, and the Middle East. Adequate data on the transfusion needs of people with thalassemia are not generally available from economically restricted countries. A small study of 330 multiply transfused patients with thalassemia in rural Bengal, India, diagnosed 3 (approximately 1%) HIV-positive patients who had received over 10 transfusions each.[159]

Appropriate Uses of Blood Transfusion

In deciding whether to transfuse, the clinician weighs the risks of obtaining potentially infected blood against the risk of the patient's not receiving blood. Often, blood is requested emergently and may not be properly screened. As shown in Table 42–4, a high number of blood transfusions are deemed inappropriate in many countries. The authors of one Tanzanian study found no difference in mortality between transfused and nontransfused anemic children, unless the child showed signs of cardiac failure, acute hemorrhage, or pneumonia.[163] However, the subjects were only followed for 8 weeks in this study, which did not take into account morbidity associated with transfusion-transmitted infections. In another decision analysis, African children with severe malarial anemia showed no transfusion benefit when the chance of survival without transfusion was greater than 95%.[164]

Researchers have attempted to quantify the risks and benefits of transfusions to certain patient populations in order to provide blood banks with precise guidelines of whom to transfuse.[165–171] Implementation of such guidelines has proven practical as well as effective. For instance, an observational study showed that Kenyan children benefited from transfusion under the following circumstances: when the hemoglobin level is less than 5.0 g/dL and when they are transfused within 48 hours of admission.[118,172]

The effect of implementing the above consensus guidelines on appropriate use of blood transfusions in Tanzania was examined, and it was found that the proportion of avoidable

Table 42–4 **Avoidable Blood Transfusions in Selected Countries**

		No. (%) Transfused			
Country	**Patient Group**	**Total**	**Avoidable**	**Year of Study**	**Reference No.**
Tanzania	Total patients	1029 (100)	334 (39)	1992	154
	Operated patients	191 (19)	26 (24)		
	Pregnant, no blood loss	52 (5)	5 (10)		
	Pregnant, acute blood loss	57 (6)	0 (0)		
	Children < 5 years	520 (51)	257 (52)		
	Children 5–15 years	43 (4)	10 (25)		
	Adults	166 (16)	36 (25)		
Kenya	Children < 15 years	83 (47)	39 (47)	1993	119
Ghana	Total patients	277 (25)	46 (17)	1991	160
	Surgical		(75)		
Tanzania	Total patients		(27–44)	1992	161
	Children < 5 years		(34–56)		
Zaire	Children		(13)	1990	149
	Adults		(21)		
Tanzania	Total patients		(35–40)	1994	162

transfusions decreased from 52% to 33% in the pediatric population after strict supervision by senior medical staff and adequate education through regular clinic meetings.[162] Physician education programs and a monitoring system to ensure adherence to established guidelines are needed to reduce waste of blood.

Blood Component Therapy

The WHO rarely recommends use of whole blood for transfusions, suggesting that at least 90% of collected units should be separated into components.[22] However, in many rural hospitals, whole blood still meets much of the transfusion need. Although some areas of Latin America follow WHO guidelines, few African countries have either the need to separate blood into components or the technology. In Mozambique, few plasma and platelet components are ordered, which may be due to poor clinician knowledge of component therapy.[152] A national survey of 604 blood banks in India found that only 21% of blood banks prepare blood-derived components; however, some component therapy does appear to be appropriately used.[77,173] The use of component therapy in other areas of the world is increasing, as reported in China, where components comprised approximately 40% of transfusions in 2000, as compared to 20% in 1996.[90] Peru's National Blood Banking Program reports that 80% of the blood is now fractionated.[174]

Alternatives to Allogeneic Blood Transfusion

Although autologous blood has been shown to decrease the need for allogeneic transfusions, it is infrequently used in economically restricted countries.[155] In a teaching hospital in Delhi, India, despite the fact that 68% of doctors reported a knowledge of autologous blood transfusion, only 22% considered autologous blood for their patients.[175] Of over 11,000 patients transfused in the Delhi teaching hospital, only 0.49% received autologous blood transfusions. Autologous blood is difficult to order before scheduled surgery in countries where many transfusions may be performed on an urgent or emergent basis.[176] Also, because autologous blood should be stored in a separate refrigerator from allogeneic blood, limited storage space augments the problem. One Nigerian hospital started an autologous blood donation program in response to rising HIV seropositivity in paid donors.[177] The researchers found that autologous blood transfusion was significantly less expensive than allogeneic, mainly due to less infectious disease morbidity in autologous blood recipients.

Quality Assurance

The WHO guidelines for quality assurance laboratory conditions should be followed in economically restricted countries whenever financial and logistic constraints allow. Laboratory infectious disease testing should be supervised, and adequate training should be provided. Protocols must be developed for procedures, reagents, techniques, equipment use, maintenance, and personnel. Performance evaluation programs should also be periodically offered.

Yet, quality assurance programs are often inadequate. Despite implementation of performance evaluations for immunohematology and serologic infectious disease testing, only a portion of blood banks typically participate.[20] In fact, when surveyed, only one third of central African hospital blood banks reported following standard practice protocols for documentation of HIV results.[148]

In summary, the laboratory testing guidelines suggested by the WHO and the PAHO are generally geared toward highly industrialized countries with low disease prevalence and adequate financial resources; the guidelines prove difficult to adhere to in economically restricted countries, which not only often face large logistic and financial constraints, but also operate in different infectious disease settings. We have reviewed the major challenges faced by many countries, including the lack of enough blood for patients, lack of reagents for screening, faulty equipment, and lack of continuing education for staff.

Innovative solutions are thus required to resolve the difficulties faced in these countries. One such solution is the option of predonation infectious disease screening of blood donors for relevant infections, aimed at decreasing blood bag waste. Although current predonation screening tests are not optimal, one can argue that suboptimal screening in many of these countries offers a better temporary solution than no screening at all. The selection of low-risk blood donors by screening, with the exclusion of paid or replacement donors, has also proven invaluable. Untested or suspect donor blood should be quarantined to prevent crossover into the blood supply. Another promising pretransfusion compatibility screening method aimed at circumventing the lack of centrifuges is the slide Polybrene method. Long-distance education programs would also prove helpful, especially to clinicians and blood banks, in an effort to promote appropriate clinical use of blood in avoiding unnecessary transfusions.

As epidemiologic studies continue gathering data on infectious disease trends in regions, certain population groups, such as the paid plasma donors with high infectious disease prevalence discovered in the 1990s, will continue to be regulated. Finally, each country's government must be dedicated to regulation and oversight of their blood banks, in an effort to optimize safety of their blood supply.

B. Complications of Transfusion

i. Infectious Complications

Chapter 43

Hepatitis A, B, and Non-A, Non-B, Non-C Viruses

Roger Y. Dodd

INTRODUCTION

Hepatitis was recognized as an adverse consequence of transfusion almost from the outset of transfusion therapy. In fact, viral hepatitis was originally classified either as *infectious* or *serum* hepatitis according to its predominant transmission mode. We now realize that infectious hepatitis was almost entirely accounted for by hepatitis A virus (HAV), whereas serum hepatitis was most likely due to infection with hepatitis B and C viruses. Other hepatitis viruses have been recognized, including hepatitis D virus (previously delta virus) and hepatitis E virus. Additional viruses have also been identified in the context of hepatitis, although they do not appear to be primary causative agents of the disease; included in this group are the hepatitis G virus and the TTV/SEN-V complex.

HEPATITIS A

Hepatitis A is usually a relatively mild disease, and there are no reports of chronic infection or disease. The mortality rate is 0.2% or less. Although symptoms may be severe, most cases are inapparent, as the seroprevalence rates may range from 5% to 74% of subsets of the U.S. population, depending on age. The incubation period averages 25 to 30 days, with a range of approximately 15 to 45 days. When symptoms are present, there may be a short prodromal phase lasting 2 to 10 days, involving fever, chills, malaise, and arthralgias. During this phase, the alanine aminotransaminase (ALT) levels rise; they peak during the appearance of the more definitive symptoms of hepatitis, namely anorexia, nausea and vomiting, and epigastric tenderness. Laboratory diagnosis is normally based on evaluation of serum ALT levels plus the use of an immunoassay for anti-HAV immunoglobulin M (IgM).

The virus is typically transmitted by the fecal-oral route. High levels of virus are shed in the feces during the prodromal stage. Food-borne outbreaks are relatively common, and the source is usually an infected food handler. Uncooked shellfish from contaminated waters are also a common source of infection. Infection is often transmitted among diapered infants in day care and in hospital nursery settings. Immune serum globulin preparations have been used prophylactically and are quite effective. However, a vaccine for HAV is now available and is recommended for those at significant risk of exposure.

The HAV is a picornavirus, classified in the genus *Hepatovirus*. As such, it is a nonenveloped virus, approximately 27 nm in diameter. It was first recognized in the 1970s on immunoelectron microscopy of fecal samples. Unlike other hepatitis viruses, HAV can be readily grown in tissue culture.[1]

Transfusion-transmitted HAV is uncommon, with approximately 25 cases reported in the literature, and a risk estimated as considerably less than 1 case per million transfused component units. Interestingly, some of the reported cases did involve young children, and there were secondary cases as a result of transmission in the nursery.[2–6] The low frequency of transfusion-transmitted HAV is usually attributed to the rather short period of viremia before the appearance of symptoms. Bower and colleagues[7] have reported, however, that HAV RNA could be detected in the blood an average of 17 days before and 79 days after the peak of serum ALT. Such findings do not necessarily correlate with infectivity. A recently published study used molecular methods to unequivocally link transfusion-transmitted HAV infection from a unit drawn 3 days before the donor's clinical presentation.[8] The relatively recent introduction of testing for HAV RNA in plasma destined for further manufacture has provided an opportunity for assessment of the prevalence of HAV viremia among routine blood donors. At least in the American Red Cross donor base, the frequency of such viremia has proven to be on the order of 1 per 2.3 million donations (data from the American Red Cross, personal communication from Susan L. Stramer).

In the United States, individuals with a history of viral hepatitis are not permitted to give blood unless they had the disease before age 11. This practice recognizes the fact that almost all hepatitis occurring before this age is due to HAV, which would not offer any risk of transmission. There are no other specific measures in place to prevent transfusion-transmitted HAV infection. However, it is usual to withdraw blood products if it is learned that the donors were recently exposed to HAV (e.g., through a known food-borne outbreak). One such outbeak occurred in 2003[9] and was the

source of significant concern, resulting in donor deferral for a period of 1 year after potential exposure. Another issue has been the extent to which HAV may be transmitted in crowded unhygienic conditions, such as those occasionally attendant on sheltering individuals during disasters. Although this was a potential concern during the hurricane disasters in 2005, no outbreak of hepatitis A was seen.

There has also been concern about transmission of HAV via some specific lots of antihemophilic factor products.[10–13] Whether the contamination derived from the plasma donors or was introduced elsewhere in the processing is unclear. However, it was clear that the solvent-detergent process failed to inactivate the contaminating virus, a finding that is not unexpected for a nonenveloped virus. As a result of these events, additional inactivation steps are used, and manufacturing pools are monitored for HAV RNA. Additionally, it is recommended that certain recipients of plasma products (including solvent-detergent–treated plasma) should receive the hepatitis A vaccine.

HEPATITIS B

Overview

Hepatitis B is the prototypic transfusion-transmitted disease. Until the early 1970s, it was considered the only form of parenterally transmitted hepatitis. Exposure to hepatitis B virus (HBV) may result in a prolonged but asymptomatic infection with the potential for high titers of circulating virus, even in the presence of a vigorous immune response. Indeed, a number of lines of evidence, including early studies of human transmission, animal inoculation, and nucleic acid amplification testing (NAT), show that such titers may reach 10^9 to 10^{10} virions per milliliter.[14]

The essentially serendipitous discovery by Blumberg and associates[15,16] of "Australia antigen" (hepatitis B surface antigen [HBsAg]) and its subsequent linkage to one form of viral hepatitis can be considered the first seminal event in the development of modern blood donor screening procedures and policies. Not only was HBsAg clearly associated with what was then known as hepatitis B, but some studies had also established that blood that was positive for the antigen clearly transmitted hepatitis B to recipients.[17]

Test methods became available around 1969 but were not uniformly adopted until about 1970 or 1971. The very first test to be implemented was Ouchterlony agar gel diffusion (AGD), which used human or animal antibodies to detect the antigen in donor serum. It is important to recognize, however, that the actual level of HBsAg in a highly infectious sample was extraordinarily high—tens to hundreds of micrograms per milliliter. The AGD test was soon replaced by directed immunoprecipitation systems, such as counterimmunoelectrophoresis, or rheophoresis, in which an electrical potential or evaporative buffer flow forced the antibodies and antigen together, thus increasing the speed and sensitivity of the test. The tests were, however, highly subjective. Some alternative methods, such as reversed passive hemagglutination, were also developed and achieved a limited degree of implementation. A historical footnote is that AGD was (retrospectively) defined as a *first-generation test,* and the agglutination and directed immunoprecipitation tests were defined as *second-generation.*

Ling and Overby,[18] working at Abbott Laboratories, soon developed a tube-based, solid-phase radioimmunoassay (RIA) for the detection of HBsAg. This method clearly had greatly improved analytical sensitivity (i.e., ≈1 ng/mL) relative to second-generation tests and was formally defined as a *third-generation test.* It was not long before the Bureau of Biologics (the 1970s equivalent of the U.S. Food and Drug Administration) published a notice in the *Federal Register*, indicating that licensure of this third-generation test was imminent and "advising" blood establishments to "become familiar" with it.

At the time of implementation of the RIA, a solution to the problem of post-transfusion hepatitis was widely anticipated. Previously, it had been recognized that second-generation tests did not eliminate all post-transfusion hepatitis—indeed, there was only about a 20% decline in reporting rates. However, by what turned out to be a coincidence, RIA generated about fivefold more reactive results than did the second-generation tests. However, it soon became apparent that most of the additional "detections" represented false-positive results. This finding was a disappointment, but it led directly to the introduction of additional confirmatory tests and an enhanced perception of the rights of the donor to be properly informed about the significance of screening test results. After a relatively short time, RIA was replaced by the enzyme immunoassay (EIA). Subsequent developments have included chemiluminescent immunoassays with analytic sensitivity of approximately 0.08 ng/mL. Additionally, NAT for HBV DNA has been developed and has seen limited use for blood donor screening since around the year 2000.

Clinical Aspects

The clinical outcomes of hepatitis B vary in terms of severity, from asymptomatic to fatal, and in terms of chronicity, from acute to lifelong. There do not seem to be any very clear predictors of the severity of disease, other than the presence of detectable levels of the viral e antigen (HBeAg) in the circulation of an infected individual. However, it is clear that the likelihood of chronic infection is very much a function of the age of the patient at the time of infection. Chronic infection is common among persons who were infected in infancy, but the frequency is reduced to 5% or fewer of persons who were infected in adolescence or adulthood.[14]

Hepatitis B differs little from other viral hepatitides in its clinical manifestations, although such manifestations may often be somewhat more severe than those of hepatitis A or C. The incubation period is about 8 to 12 weeks, although it may extend to 6 months or longer, particularly if hepatitis B immune globulin has been used for postexposure prophylaxis. The majority of infections appear to be asymptomatic, although up to 30% of infected adults experience some level of jaundice. Hepatitis B may be fulminant and leads to death in about 0.5% to 1% of cases. As previously pointed out, a variable proportion of infections, irrespective of the occurrence of acute disease, resolve without further clinical symptoms with the development of essentially lifelong immunity, as indicated by the development and maintenance of detectable levels of antibodies to HBsAg (anti-HBs). However, it should be noted that such individuals may continue to harbor virus in the liver, as demonstrated by the occurrence of hepatitis B in transplanted livers from anti-HBs–positive donors.[19]

Chronic hepatitis B may be asymptomatic, but there is a wide range of symptomatic outcomes, up to and including fatal disease. As with other chronic hepatitis viruses, a proportion of patients may eventually demonstrate cirrhosis. In addition, chronic hepatitis B infection may result in the development of primary hepatocellular carcinoma, probably as a direct result of viral integration into the host cell genome. Unlike with hepatitis C, liver cancer induced by HBV may occur in the absence of cirrhosis.

There are also a number of extrahepatic manifestations of HBV infection, including rashes, arthritis, vasculitis, and glomerulonephritis.[14] Most are related to the formation of immune complexes involving HBsAg.

Treatment

There is no established treatment for acute hepatitis B, but therapies are approved for chronic disease. Currently, a 4- to 6-month course of interferon alfa-2b (5 to 10 million units, three times per week) is recommended. Improvement, as evidenced by HBe seroconversion, normalization of ALT, and sustained loss of HBV DNA in the circulation, may be seen in 20% to 30% of treated patients, although only about 10% lose HBsAg expression. Similar results are seen after a 12-month course of lamivudine, and response rates improve with more prolonged therapy.[20] Subsequently, more detailed recommendations have been published, establishing a variety of regimens for differing presentations of hepatitis B.[21] In general, in addition to interferon, lamivudine and adefovir are recommended for a year or more. Indicators of effective treatment include loss of detectable HBeAg and/or normalization of ALT levels. Pegylated interferon and lamivudine combination therapy seems most effective for HBeAg-positive patients.[22] Similarly prolonged treatment with adefovir appears to be effective for HBeAg-negative cases.[23]

Epidemiology

Hepatitis B virus is transmitted parenterally. Key risk factors for HBV include injection drug use; sexual exposure (both male-to-male and heterosexual); other parenteral exposures to blood and body fluids, including nonsterile tattooing and body piercing, as well as more subtle exposure via minor skin abrasion; and familial exposure. There is also geographic risk related to residence in areas of high prevalence. Transmission occurs readily, as a consequence of the high titers of infectious virus found during acute and chronic infection. In addition, infection may be transmitted from a viremic woman to her infant during birth.

In countries such as the United States, which have relatively low prevalence and incidence rates for HBV, most infection occurs horizontally between adults. Because adult infection generally has an acute outcome, opportunities for secondary transmission tend to be limited. Some behavior patterns, however, such as sharing of needles during injection drug use or frequent sexual contact with many partners, do result in a very high incidence of HBV infection. In areas with a high prevalence of chronic infection, both horizontal and perinatal patterns of infection occur, and the latter frequently leads to chronic infection and a prolonged carrier state. Thus, high prevalence rates are maintained; such a situation is seen in parts of the Far East, for example.

The overall prevalence of serologic evidence of HBV infection in the United States is approximately 5.6%, as indicated by measurements of HBsAg and antibodies to hepatitis B core antigen (anti-HBc).[24] However, infection rates are much higher among groups engaging in risky behaviors, such as male-to-male sex and injection drug use. The national prevalence of active infection, as defined by the presence of HBsAg is much lower, however—0.1% or less. In contrast, some parts of the world have seroprevalence rates of 50% or greater, with correspondingly high rates of active infection. Within the United States, the prevalence and incidence of HBV markers among blood donors are much lower than those seen in the overall population, reflecting the efficacy of measures used for donor selection.[25] Indeed, many of the donor screening questions in current use derived from efforts to minimize the transmission of hepatitis B. Additionally, questions used to reduce the risk of transmission of human immunodeficiency virus (HIV) are also likely to have had a significant impact on the number of infected donors.

There is no question that HBV vaccination policies are having an impact on the incidence (and ultimately the prevalence) of HBV infection. Widespread vaccination of infants offers the promise of interrupting maternal-child transmission of the virus and thus reducing the frequency of chronic infection and its sequelae. In the United States, there has been a clear decline in the frequency of reported cases of HBV infection,[26] which has been reflected in the continuing decrease in the frequency of HBV marker rates (particularly anti-Hc) among U.S. blood donors.

Virology

The human hepatitis B virus is the prototype of a small group of unusual DNA viruses known as the Hepadnaviridae. They have a lipid envelope and a small, partially double-stranded DNA genome, the full-length section of which has approximately 3200 bases, encoding four overlapping reading frames. DNA replicates in the hepatocyte nucleus by means of a unique mechanism involving a viral DNA polymerase and an RNA intermediate that is reverse transcribed. The transcription system does not have any inherent error-correction mechanism, so there is a much higher than usual frequency of nucleic acid substitution and thus mutation during viral replication. The virus itself is approximately 42 nm in diameter. The outer envelope is lipoprotein, antigenic, and known as HBsAg. The virus-specific antigen is termed "a," and there are a variety of antigenic subtypes, broadly and simplistically defined as two pairs of mutually exclusive alleles: d,y and w,r. The w determinant has itself been further characterized into four subspecificities. The major significance of these antigenic subtypes has been their use in epidemiologic studies.

Assessment of genome sequence variation of the virus has led to the recognition of six genotypes, A through F, on the basis of sequence variations of 8% or more. There is no systematic relationship between genotypes and antigenic subtypes. Genotyping may supplant antigenic subtyping for definition of the molecular epidemiology of HBV infection. Additionally, genotypes are more likely to reflect variations in the biology of different viral isolates.

Perhaps the most intriguing characteristic of HBV is that active HBV infection leads to copious overproduction of HBsAg, which is released into the circulation as self-assembled spheres and tubules, 22 nm in diameter. As already mentioned, HBsAg was first recognized (as Australia antigen) by Blumberg and associates.[15,16] The subsequent finding that

HBsAg is associated with hepatitis B led directly to blood donor testing for the antigen in the early 1970s and indirectly to the recognition of other hepatitis viruses.

The inner capsid of the virus has a different immunologic specificity and is known as the *hepatitis B core antigen*. This antigen was first recognized on immunoelectron microscopy of detergent-treated samples of virus-containing blood.[27] The core antigen is not normally detectable in serum or plasma, because it is located within the virus. It may, however, be detected in the nuclei of liver cells with active viral replication. Also coded by the gene for the core antigen is a smaller polypeptide sequence, masked in the full-length transcript, that includes a separate antigenic specificity termed *HBeAg*. This smaller peptide can be found free in the circulation during active infection.[28]

Laboratory investigations have clearly demonstrated the sequence of appearance of plasma markers of HBV infection.[29] Some 25 days after exposure to the virus, HBV DNA may be detected at low levels (hundreds or thousands of copies per milliliter). About 25 days later, these levels rise significantly, and at the same time, HBsAg becomes detectable by relatively insensitive techniques such as EIA. Generally, this period coincides with the appearance of symptoms of hepatitis and elevated liver function markers. About 4 to 8 weeks after the initial appearance of HBsAg, anti-HBc may be detected in the circulation.

A specific test for IgM anti-HBc is available and is extremely useful for diagnosis of HBV infection. With use of the available tests, IgM antibody may be detectable for 3 to 6 months. The IgG antibody persists over many years, whether or not the infection is frankly chronic. In the event of self-limited infection, HBsAg may be detected for about 6 to 12 weeks, but its level declines as anti-HBs becomes detectable. The presence of anti-HBs is usually taken to signal resolution of infection and the absence of infectious virus in the circulation. However, as pointed out previously, virus may persist in the liver.

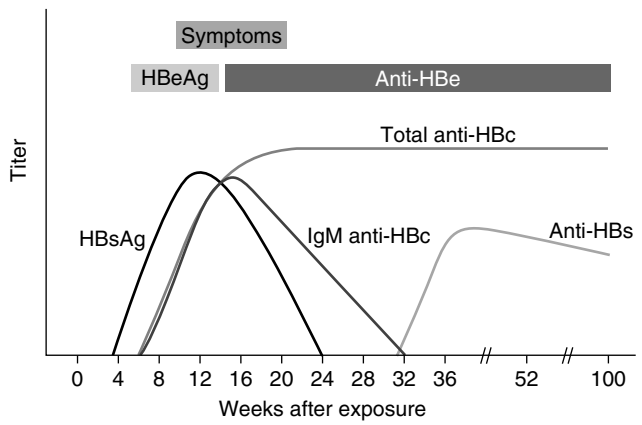

Figure 43–1 Typical serologic course of acute hepatitis B virus infection with recovery. Serologic markers of hepatitis B virus (HBV) infection vary, depending on whether the infection is acute or chronic. The first serologic marker to appear after acute infection is hepatitis B surface antigen (HBsAg), which can be detected as early as 1 or 2 weeks and as late as 11 or 12 weeks (mode, 30–60 days) after exposure to HBV. In persons who recover, HBsAg is no longer detectable in serum after an average of about 3 months. Hepatitis B e antigen (HBeAg) is generally detectable in patients with acute infection; the presence of HBeAg in serum correlates with higher titers of HBV and greater infectivity. A diagnosis of acute HBV infection can be made on the basis of the detection of immunoglobulin M (IgM) class antibody to hepatitis B core antigen (IgM anti-HBc) in serum; IgM anti-HBc is generally detectable at the time of clinical onset and declines to subdetectable levels with 6 months. IgG anti-HBc persists indefinitely as a marker of past infection. Anti-HBs becomes detectable during convalescence after the disappearance of HBsAg in patients who do not experience chronic infection. The presence of anti-HBs after acute infection generally indicates recovery and immunity from re-infection. (Courtesy of Centers for Disease Control and Prevention; from a publicly available slide set.)

Diagnostic Testing and Donor Screening

The primary diagnosis of hepatitis relies on cinical symptoms and the results of liver function tests. However, such tests do not permit differentiation of the etiology, and serologic testing is required. During the course of infection, a variety of patterns of expression of different markers is seen. To some extent, it is possible to define the stage of infection on the basis of these patterns.[14,28] The simplest situation is in acute infection (or the early stages of an infection that becomes chronic), in which the most reliable diagnostic marker is IgM anti-HBc. Figures 43–1 and 43–2 illustrate the patterns of marker expression in acute self-limited infection and chronic infection, respectively. Table 43–1 summarizes the interpretation of differing patterns of expression of key diagnostic markers.

In the United States, all whole blood donations are tested for HBsAg and for anti-HBc to reduce the risk of transmission of HBV. Interestingly, testing for anti-HBc was initially introduced in 1986 as a surrogate test for infectivity for non-A, non-B hepatitis. In the face of sensitive tests for hepatitis C virus (HCV), there is now no such surrogate value for anti-HBc testing. In fact, the actual benefit of anti-HBc testing in prevention of HBV infection is unclear, although it has been shown that, among voluntary donations that are anti-HBc positive but HBsAg-negative, somewhat fewer than 1% have detectable HBV DNA.[30] Many years ago, anti-HBc testing was also thought to be beneficial in detecting infectious samples during a window when HBsAg was no longer detectable and effective levels of anti-HBs had not developed. This window is no longer apparent with HBsAg tests at their current levels of sensitivity.

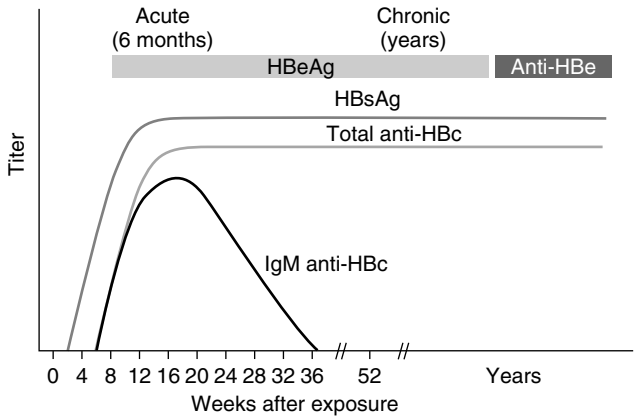

Figure 43–2 Typical serologic course of progression to chronic hepatitis B virus infection. In patients with chronic hepatitis B virus (HBV) infection, both hepatitis B surface antigen (HBsAg) and immunoglobulin G (IgG) antibody to hepatitis B core antigen (anti-HBc) remain persistently detectable, generally for life. Hepatitis B e antigen (HBeAg) is variably present in these patients. The presence of HBsAg for 6 months or longer generally indicates chronic infection. In addition, a negative test result for IgM anti-HBc together with a positive test for HBsAg in a single serum specimen usually indicates that an individual has chronic HBV infection. (Courtesy of Centers for Disease Control and Prevention; from a publicly available slide set.)

Table 43–1 **Interpretation of Results of Hepatitis B Test Panel**

Tests	Results	Interpretation
HBsAg Anti-HBc Anti-HBs	Negative Negative Negative	Susceptible
HBsAg Anti-HBc Anti-HBs	Negative Positive Positive	Immune because of natural infection
HBsAg Anti-HBc Anti-HBs	Negative Negative Positive	Immune because of hepatitis B vaccination
HBsAg Anti-HBc IgM anti-HBc Anti-HBs	Positive Positive Positive Negative	Acutely infected
HBsAg Anti-HBc IgM anti-HBc Anti-HBs	Positive Positive Negative Negative	Chronically infected
HBsAg Anti-HBc Anti-HBs	Negative Positive Negative	Four interpretations possible*

*The patient (1) may be recovering from acute HBV infection; (2) may be distantly immune (the test is not sensitive enough to detect very low levels of anti-HBs in serum); (3) may be susceptible with a false-positive anti-HBc test result; or (4) may have an undetectable level of HBsAg in serum, so is actually a carrier.

Anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen; HBsAg, hepatitis B surface antigen; Ig, immunoglobulin. Courtesy of Centers for Disease Control and Prevention.

Estimates of the residual risk of HBV transmission are surprisingly high; in 1996, Schreiber and colleagues[31] suggested a figure of 1:63,000 donations. Some researchers express concern that this figure may be inappropriately high, on the basis of questions about the underlying assumptions and the absence of observed post-transfusion hepatitis B. In fact, in 2001, even with the same assumptions made by Schreiber,[31] the risk of HBV transmission was estimated to have at least halved as a result of the decreased incidence of HBV among U.S. donors. The most recent estimate of the residual risk of post-transfusion HBV infection is 1:205,000 among repeat donations or 1:144,000 among all donations, in the absence of NAT.[32,33] However, such estimates inherently depend on a number of assumptions and extrapolations, and the frequency of observed cases of post-transfusion hepatitis B is insufficient to support this estimate. Additionally, it seems likely that many of the cases of post-transfusion hepatitis that are reported are not, in fact due to transfusion transmission, as recently shown by Alter and her associates (presented at the Advisory Committee on Blood Safety and Availability, August 26 to 27, 2004; see http://www.hhs.gov/bloodsafety/presentations/MiriamAlter.pdf). She found that only one of 49 cases of supposed post-transfusion hepatitis could be unequivocally linked to transfusion of an infectious unit. On the other hand, there is little in the way of organized lookback for hepatitis B, at least in the United States, but data from Japan clearly show that window-period HBV infection may occur.

Nucleic acid amplification testing for HBV is available and has been implemented in a number of countries around the world. As of late 2005, one test had been licensed for use in the United States, and clinical trials have been completed for another, in a triplex format that includes HIV and HCV testing.[34] However, it is clear that the current minipool approach will not have any significant benefits, because NAT has essentially the same sensitivity as the newest of the serologic tests for HBsAg.[35] Nevertheless, clinical trials of one of the U.S. tests did generate a measurable yield of about 1:250,000 HBV DNA-positive, seronegative donations, even in a pooled testing format. Such NAT for HBV DNA has been implemented in some European locations (where anti-HBc testing is not performed) and by some manufacturers of pooled plasma products.[36] The potential added value of single-unit (i.e., nonpooled) NAT for HBV DNA has not been well-defined, although it will certainly prevent cases of post-transfusion HBV infection. Perhaps the greatest value of HBV NAT will be in regions where testing for anti-HBc is not used, because it could detect those samples that are positive for anti-HBc and viremic for HBV. However, such samples generally have a low level of DNA, and a sensitive test will be needed.

Mutants and Vaccines

A number of mutants of HBV have been recognized, and there is evidence that the representation of such mutants is increasing. Perhaps of greatest concern for transfusion medicine are those mutants that do not express HBsAg.[37–39] This group includes those described as *escape mutants*—a term signifying an ability to evade the protective effects of HBV vaccines (which are currently based on HBsAg). However, infection with these mutants still provokes the formation of detectable levels of anti-HBc, so that most such infections would be detected, at least in the United States and other countries where anti-HBc testing of donations is routine.

Currently available hepatitis B vaccines prepared from recombinant antigens are safe and effective and are recommended for universal use in infants. It is to be expected that consistent use of these vaccines will eventually lead to significant reduction in HBV infection rates and thus to a decline in the prevalence of chronic infection. Current vaccines provoke only anti-HBs and so do not interfere with routine blood donation testing. However, it should be noted that HBsAg itself may be detectable in the circulation for a few days after inoculation. Although there is no need to defer a recent vaccine recipient for safety reasons, it is wise to avoid collection of blood from such a person for about 7 days after vaccination. Otherwise, there is a risk that the donor will be confirmed positive for HBsAg and will thus be deferred. Finally, although the risk of transmission of HBV by blood components has almost been eliminated and although there should be no cases from manufactured plasma products as a result of careful donor management and viral inactivation of the final product, chronic users of blood and blood products should certainly receive the HBV vaccine.

HEPATITIS D

Hepatitis D is caused by a small satellite virus, originally termed the *delta virus*, that can replicate only in the presence of HBV infection. The virus is an RNA virus and, almost unique among animal viruses, has a circular genome. It encodes a single peptide, originally observed in infected hepatocytes and termed *delta antigen*. The infectious form of HDV is

coated with HBsAg. Co-infection with HBV and HDV results in a more serious disease than does HBV infection alone. In truth, HDV has little current relevance to transfusion safety, because measures designed to detect infectivity for HBV also detect all individuals co-infected with HDV.[40,41]

HEPATITIS E

Hepatitis E virus (HEV) causes an epidemic form of hepatitis that is self-limited.[42,43] The disease is somewhat similar to hepatitis A, although it is much more severe in pregnancy. Transmission is by the fecal-oral route and is most often water-borne. The virus is related to the calicivirus group and, as such, is a nonenveloped virus that has an RNA genome. Although there is some evidence (based largely on seroprevalence studies) that HEV is present in the United States, it is found predominantly in tropical countries. Indeed, most cases identified in the United States appear to have resulted from infections that occurred in countries where HEV is endemic. HEV infection is self-limited and acute, and it has generally been thought that there is little risk of transmission by transfusion. Until recently, no cases of transfusion-associated HEV infection have been reported.[44] However, a number of recent cases of such transmission have been reported from nonendemic areas, emphasizing that acute infections are also transmissible by transfusion, as long as there is an asymptomatic viremic phase.[45,46] This has, of course, been abundantly illustrated by the example of West Nile virus in the United States.[47]

HEPATITIS G VIRUS/GBV-C

The vast majority of cases of post-transfusion hepatitis have been shown to be caused by HBV or HCV. Nevertheless, there continue to be some residual cases of hepatitis associated with transfusion. For example, in Alter's continuing studies at the National Institutes of Health, approximately 12% of cases of non-A, non-B hepatitis could not be attributed to either HBV or HCV. These residual cases appear to be mild and self-limited, and some may not even have an infectious etiology. Such cases have, however, led to a continuing search for additional hepatitis viruses. The first of such putative hepatitis viruses was identified by two separate groups in the late 1990s. In one case, scientists at Abbott Laboratories looked for genomic sequences related to those of an existing isolate known as the *GB virus* (GBV), which had previously been associated with hepatitis in a physician. Three viruses were identified, one of which (termed GBV-C) was found among a number of human sources.[48] Working in parallel, but using a different approach, scientists at Gene-Labs isolated viral RNA sequences and characterized a virus they termed *hepatitis G virus* (HGV).[49] It is generally accepted that these two isolates were, in fact, representatives of essentially the same virus group, which is now known as HGV.

HGV, like HCV, appears to be closely related to the Flavivirus group. It is found among a relatively high proportion of the normal population, as exemplified by blood donors. Its presence has been demonstrated both by seroprevalence studies, in which the frequency of antibodies is 3% to 15%, and more interestingly by detection of viral RNA in the plasma of 1% to 3% of normal subjects.[50] Perhaps not surprisingly, the virus is readily transmissible by transfusion and is found at high prevalence among individuals who have undergone multiple transfusions. However, it has not proved possible to demonstrate that infection with HGV is associated with hepatitis or even with signs of mild liver disease, such as elevated ALT levels. Indeed, HGV appears to be a virus that is currently in search of a disease. The term *hepatitis* in its name may be a misnomer, attributable only to the fact that the virus was found in association with hepatitis in the first place. It is also important to recognize that the worldwide distribution of HGV clearly shows that it is not a new virus but rather one that has coexisted with humans for many centuries.

There have, however, been some intriguing observations that clearly suggest that HGV/GBV-C may have an impact on the course of HIV disease. For example, studies have shown lower mortality among co-infected individuals relative to those with HIV only.[51,52] The mechanism for this effect is unclear, but it may be due to the effects of infection on the levels of a number of chemokines.[53]

TTV AND SEN-V

Curiously, another pair of viruses were separately identified among individuals with hepatitis and were also shown to be poorly, if at all, associated with hepatitis. These viruses were also found to cause prolonged viremia and, in some cases, turned out to be present in up to 90% of the population. Like HGV, they were readily transmitted by transfusion. Both viruses were thought to be representatives of the circovirus group: small, nonenveloped viruses with a circular DNA genome. This group of viruses had not previously been described among humans.

Workers in Japan used representational difference analysis to isolate DNA sequences from three patients with unexplained post-transfusion hepatitis. The sequence was established as viral, and the virus was named *TTV,* reflecting the initials of the patient from whom it was isolated.[54] A considerable amount of research has revealed some of the key features of this agent.[55] It is a small virus with a covalently closed, circular DNA genome of approximately 3800 bases. The virus is thought to be nonenveloped and is most closely related to the circoviruses, which are responsible for a number of diseases in plants and a handful of mammalian and avian disease states. The classification of TTV is currently incomplete, and proposals have been made to place it in at least two genera. What has become apparent is that TTV is a member of an extremely diverse group of viruses, as demonstrated by considerable variation in genomic sequence.

Epidemiologic studies have confirmed that TTV is a widely distributed virus and have clearly established that it is transmissible by transfusion. Interestingly, it also appears to be transmitted by the vertical, fecal-oral, and perhaps other routes.

A key issue is the clinical significance of this group of viruses. Although the original source of the virus and its apparent association with ALT elevations implied that TTV was indeed a hepatitis virus, this identification no longer seems tenable. Indeed, there are far more infections without ALT elevations than with such evidence of liver disease. Even in clear, transfusion-associated transmission of TTV, the recipients did not manifest ALT elevations in any pattern that could be associated with the infection. Thus, at this stage, there is little evidence that this virus expresses

any pathogenic potential. However, it is certainly too early to conclude that this entire group of viruses is without any clinical significance.

After the recognition of TTV, the search for hepatitis viruses continued, and Primi and colleagues[56,57] used degenerate primers derived from TTV to probe samples from selected patients. An isolate was identified and named *SEN-V* (after the initials of the source patient, an HIV-infected injection drug user). Eventually, at least eight different strains were isolated, termed A through H. The SEN group has been shown to be one branch of the TTV group, seeming to share its epidemiologic characteristics. Although two of the strains (D and H) have been associated with evidence of transfusion-associated hepatitis, a causal relationship has not been established.[56,57]

Thus, attempts to define the etiologic agent(s) of non-A through E hepatitis do not appear to have been successful to date. The availability of powerful genomic techniques has certainly led to the recognition of previously undescribed viruses, but it has not been possible to associate any particular disease with these remarkably widespread viruses. No doubt other such orphan viruses will be identified. However, it will be important to avoid an automatic assumption of causality when such viruses are isolated from patients with any given disease state. It may also be important to question whether all residual transfusion-associated hepatitides do indeed have an infectious etiology.

Chapter 44

Hepatitis C

Roger Y. Dodd

INTRODUCTION

For many years, hepatitis C was the most common infectious complication of blood transfusion in the United States. Indeed, a number of studies in the 1970s showed that more than 10% of blood recipients had biochemical evidence of what was then termed *non-A, non-B hepatitis* (NANBH).[1,2] Subsequently, almost all of these cases were shown to be due to infection with the hepatitis C virus (HCV). Fortunately, the implementation of increasingly sensitive tests for HCV infection has now reduced the incidence of post-transfusion hepatitis C infection to levels that are essentially undetectable by direct study; by early 2001, the risk was estimated at about 1 infection per 1.4 million component units.[3]

THE DISEASE

The symptoms of acute hepatitis C do not differ significantly from those of other viral hepatitides, although they may be somewhat less severe than those of hepatitis B. The incubation period is 7 to 8 weeks, but a wide range has been noted. It has been estimated that about 25% of acute cases may be accompanied by symptoms that, in some cases, may be quite mild. When present, symptoms include fatigue, anorexia, abdominal pain, and weight loss. A proportion (perhaps 20% to 30%) of patients with acute hepatitis C may become jaundiced. Symptoms may last for up to 10 weeks. Alanine aminotransferase (ALT) levels are elevated during the acute phase; such elevations tend to be moderate (i.e., around 300 to 400 IU/L) but may be quite high (up to 2000 IU/L). Acute disease is rarely fatal, with mortality rates of 1% or less.

Approximately 20% of acute infections resolve. The remaining 80% (whether symptomatic or not) become chronic. The natural history of chronic HCV infection is not completely understood. Such chronic infections may last for the lifetime of the patient, although there is growing evidence that 26% to 45% of these cases may eventually resolve, as shown by the disappearance of detectable HCV RNA in the circulation and in some instances by the eventual loss of detectable antibody.[4] Many infected individuals may remain completely asymptomatic for several years (perhaps even their whole lives), but a good number have histologic evidence of liver disease, including hepatitis, fibrosis, and cirrhosis. In some cases, hepatocellular carcinoma develops.

Alter and Seeff[4] have published a framework representing the outcome of HCV infection that is based on a large number of published studies. They conclude that 20% of infected individuals resolve the acute infection. Of the remaining 80% who become chronically infected, 30% demonstrate a stable chronic hepatitis with a favorable outcome. Another 30% have severe, progressive hepatitis, and the remaining 40% may have some variable progression. Prospective studies have shown, however, that chronic symptomatic hepatitis may take an average of 10 to 14 years (and, frequently, much longer) to develop, whereas cirrhosis may take an average of 21 years and hepatocellular carcinoma almost 30 years. Although life-threatening outcomes may be uncommon or considerably delayed, it is still true that the consequences of HCV infection are the leading indicator for liver transplantation in the developed world.

From the perspective of transfusion medicine, this pattern of disease has two important consequences. First, although the immediate consequences of post-transfusion hepatitis C may seem to be largely trivial, the long-term outcomes cannot be ignored. Second, the preponderance of asymptomatic, chronic infection leads to a relatively large population of individuals who are at risk of transmitting the infection via blood donation.

TREATMENT

In 1997, a National Institutes of Health Consensus Development Conference gave recommendations for treatment of chronic hepatitis C, applicable to individuals with significant histologic findings on biopsy, presence of HCV antibody, elevated ALT, and detectable levels of HCV RNA.[5] In brief, such patients should initially be treated with 3 million units of interferon alfa three times a week for 12 months. In the absence of any response (i.e., normalization of ALT and loss of detectable HCV RNA), this therapy should be discontinued after 3 months and the patient should be considered for combination therapy with interferon and ribavirin. Overall, about 50% of patients show temporary improvement with this regimen, but ultimately, only about 25% of all patients show definitive resolution of disease. A subsequent Consensus Development Conference in 2002 updated these recommendations, emphasizing the value of combination therapy.

These treatment recommendations have been updated by Liang and colleagues[6] on the basis of experience with combination therapies. In fact, a review of two studies revealed that a sustained response to interferon alone was observed in 29% of patients after treatment for either 24 or 48 weeks.[6] However, among those receiving combination therapy (interferon plus ribavirin), 33% showed a sustained response at 24 weeks, and 41% showed such a response after 48 weeks of therapy. It was also noted that treatment for more than 24 weeks was unnecessary in patients with HCV subtypes

2 and 3, because of the greater responsiveness of these subtypes to treatment. A number of studies have indicated that pegylated interferon is more effective than the standard product; it is now the preferred version, particularly for treatment of recurrent disease.[7,8] Detailed recommendations for diagnosis, management, and treatment of hepatitis C have recently been published by the American Association for the Study of Liver Diseases.[9] Current therapeutic approaches result in a sustained response in 42% to 82% of patients with chronic disease, depending on the viral genotype.

EPIDEMIOLOGY

Hepatitis C virus is globally distributed and, with a few notable exceptions, the seroprevalence rate is remarkably constant from one region to another, usually on the order of 1% to 2%.[10] Although some countries or localities have startlingly high rates, these may be due to cultural factors, including the use of traditional medicine practices; in Egypt, for example, numerous infections were attributed to a program involving injections for control of schistosomiasis.[11] In the United States, the overall seroprevalence rate has been estimated at 1.8%, and 65% of persons infected with HCV are age 30 to 49.[12]

Transmission of HCV is primarily confined to parenteral routes. In the United States, it is clear that many of the currently identified infections are a result of previous exposure via illegal injection of drugs. In addition, many infections are believed to have resulted from blood transfusions given before the availability of sensitive tests.[13] Other epidemiologic associations are the use of clotting factor concentrates before the implementation of effective viral inactivation in 1987, exposure in a health care setting, household exposure, multiple sexual partners, and low socioeconomic level.[14]

There has been considerable speculation about the natural transmission routes of HCV, which have presumably been responsible for maintaining the baseline viral prevalence levels over centuries or even millennia. Some evidence exists for sexual and perinatal transmission, but in both cases, it seems likely that transmission may occur only during early acute infection. HCV infection does not show the strong association with male-to-male sex that has been seen for hepatitis B and human immunodeficiency viruses (HIVs).

The incidence of new HCV infections has declined by 80% or more since 1989. Clearly, there has been a major reduction in transfusion transmission of the virus, and the majority of new infections (about 60%) are attributable to injection drug use. Even though incidence is declining, it is anticipated that the burden of HCV disease will continue to rise over the foreseeable future because of the large number of chronically infected individuals.[10,15]

Studies on the epidemiology of HCV infection among blood donors are of significant importance in the context of strategies for donor selection and questioning. Conry-Cantilena and associates[16] studied a population of 481 blood donors who were found to be reactive in screening tests for anti-HCV. Among the 241 with positive strip immunoassay (SIA) results, 27% had a history of transfusion, 68% had used cocaine intranasally, 42% had a history of intravenous drug use, and 53% reported a history of sexual promiscuity; ear-piercing among men was also significantly associated with a positive test result. Many of these risk factors were confounded. Nonetheless, these observations prompted the institution of donor questions regarding intranasal cocaine use; a formal requirement for this question was subsequently eliminated, however.

It is of interest to note that, in a study performed in blood donors who tested positive for HCV RNA but negative for HCV antibody, 29.2% reported recent intravenous drug use. A history of recent incarceration was independently associated with nucleic acid amplification test (NAT) positivity.[17] The prevalence of HCV infection in current injection drug users is estimated to be 79%, although this rate does appear to be declining.[10] Donor history questioning can certainly be improved, but it is unclear how to obtain more accurate information on previous illicit drug exposures, whether they be recent or many years ago. Fortunately, individuals with past histories do not contribute to window period risk.

VIROLOGY

The hepatitis C virus was first recognized in 1989 as the principal etiologic agent of NANBH. A small RNA genome segment was isolated from a presumptive viral pellet prepared from the plasma of an experimentally infected chimpanzee. When the encoded peptide was expressed in bacteria through the use of a lambda phage vector, it was reactive with antibodies present in convalescent serum from a patient with NANBH.[18] This RNA fragment, termed *5-1-1,* was used as a basis for the eventual sequencing of the entire genome of the virus. The 5-1-1 sequence was also used to develop the capture reagent (the c100-3 peptide) incorporated into the initial version of an HCV antibody enzyme immunoassay (EIA). This peptide represents a portion of the NS3 region of the HCV genome.[19] Subsequently, additional peptides have been expressed and incorporated into improved versions of the HCV antibody test.

The virus itself is an enveloped, single-strand RNA virus now classified as a separate genus (*Hepacivirus*) within the Flaviviridae. It has a positive-strand genome of barely less than 10,000 bases. The functional organization of the genome has been well-defined.[20]

Recently, there has been notable success in establishing a laboratory culture system for the virus, in which a replicative form of the viral genome has been used to infect cells in vitro. Virus produced from such systems has been shown to be infectious for chimpanzees.[21,22] These culture systems offer considerable promise for the further study of the virus.

Hepatitis C virus is characterized by considerable genetic variability, expressed at three levels: genotype, subtype, and isolate. There are six major genotypes of HCV, designated by the Arabic numerals 1 to 6. The RNA sequence varies between genotypes by some 25% to 35%, and this level of differentiation has probably emerged over periods of 500 to 2000 years. Subtypes within a genotype, designated by lowercase letters (a, b, etc.), represent RNA sequence variation of 15% to 25% that evolved over about 300 years. Individual isolates within a subtype may vary by 5% to 10% in RNA sequence.[23–27] Overall, these studies indicate that the frequency of major subtypes in the United States is as follows: 1a, 42.6%; 1b, 29.2%; 2a, 2.7%; 2b, 8.1%; 3a, 4.7%.

Additionally, there are hypervariable regions in the genome, and many quasispecies of HCV are likely to develop in an individual patient over time. In general, any variation below the level of subtype is unlikely to be reliable enough to differentiate sources of infection. The distribution of HCV

subtypes may change with geography. It has been suggested that the clinical outcome of HCV infection and the response to treatment may vary with subtype. Genotypes 2 and 3 are more responsive to treatment than the more common subtypes 1a and 1b.[5,9,28,29]

The sequence of events after infection with HCV has been well-characterized at the level of viral markers in the circulation. Antibodies may be detected by version 3.0 tests an average of 70 days after exposure, although this period may be quite variable.[30,31] However, some 40 to 60 days prior to the appearance of such antibodies, HCV RNA may be detected in the plasma. The HCV RNA levels rise rapidly (over a few days) to 10^5 to 10^7 copies/mL. This level is generally maintained at least until significant levels of antibody are expressed. It is now apparent that a soluble viral core antigen is also present and can be detected once the RNA levels exceed about 50,000 copies/mL.[32,33] Elevated levels of ALT are frequently observed a few days before antibodies are detectable, but always after the steep rise in RNA levels. Interestingly, there is growing evidence that there may be occasional low levels of viral RNA in the circulation during the early eclipse phase, after infection and prior to the steep rise to peak levels of RNA.[5,29]

The implementation of widespread NAT for HCV RNA has been shown to detect a meaningful number of RNA-positive, anti-HCV–negative donations. Stramer and colleagues[34] reviewed the results of the first 3 years of testing in the United States. Among almost 40 million donations tested by the Chiron/Gen-Probe or Roche assays in small pools of plasma samples (16 and 24 samples per pool, respectively), 170 RNA-positive, anti-HCV nonreactive samples were identified. This reflected an overall rate of 1 in every 230,000 donations. Although there was no significant difference in the rates from the two different HCV RNA tests, the rate amongst donations tested by the more sensitive test for anti-HCV was 1 in 270,000. Within the Red Cross system, the rate was 1:251,000 for the first 3 years of HCV NAT, increasing to 1:221,000 in the following 2 years. The increase was not statistically signficant. Overall, of 156 evaluable cases, 51 would have been excluded as donors as a result of other test results, primarily ALT elevations, which occurred among 46 of the 51.[34] Thus, in retrospect, ALT testing probably did have a modest impact on blood safety, but at significant cost in terms of blood supply. These data, along with other information showing that donor ALT levels were of little or no demonstrable value for interdicting other supposed transfusion-transmitted hepatitides, led to its elimination for blood component testing.

In Stramer's study, RNA-positive donors were entered into follow-up investigations. It was found that 75 of 90 enrolled donors seroconverted, as detected in samples collected a median of 35 days post-donation. The majority of those who failed to seronconvert had only been followed for 12 to 58 days. In a more comprehensive study of 67 RNA-positive donors, 7 failed to complete follow up, 2 had abortive infections, and 3 did not seroconvert after periods of 1.5 to 3 years. It is of interest to note that the median time to observed follow-up is approximately 50% of the supposed window period, although 35 days is probably something of an overestimate because of the sampling intervals in the study.[34]

Once antibodies are detectable, RNA levels may decrease or become variable. In the evaluation of samples from blood donors, HCV RNA is detected in about 80% of samples that are reactive on a version 3.0 EIA and confirmed reactive on the version 3.0 SIA.[35] The frequency of RNA detection declines with the strength of the antibody response (as defined by the number and intensity of bands on the SIA).[36] It seems likely that the antibody-positive, RNA-negative samples actually represent resolved infections. In some cases, antibodies may eventually decline to undetectable levels.

There is a vigorous humoral and cytotoxic immune response to HCV, but in most cases, it is clearly unable to eliminate the virus. The mechanisms underlying the ability of the virus to escape the immune response are not well understood. The infecting virus often generates a wide variety of quasispecies; further, the representation of these variant forms changes rapidly over time.[20,37] Yet it appears that these changes may contribute only in part to viral persistence.

SEROLOGIC TESTS FOR HCV INFECTION

Two licensed EIA tests for HCV antibodies are currently available in the United States. Although both use recombinant viral antigens as the solid-phase capture reagent, they differ in their physical format and in the number and nature of viral antigens used (Table 44–1). The test manufactured by Ortho Clinical Diagnostics uses a microplate solid phase and has been designated as a 3.0 version by the manufacturer. The peptides that are coated onto the microplate well are known as c22-3 from the C (core) region, c200 from the NS3-NS4 regions, and an NS-5 peptide. The test manufactured by Abbott Laboratories uses a polystyrene bead solid phase and is designated as a version 2.0 test. The capture reagents for this test are c22-3, and c33 and c100-3 (both from the NS3/NS4 region). Both test procedures use an antiglobulin conjugate to detect the analyte antibodies. The performance characteristics of the tests, representing the manufacturers' claims (see Table 44–1), have been validated by extensive clinical trials, and the tests have been licensed as biologics by the U.S. Food and Drug Administration (FDA). Other tests on fully

Table 44–1 **Enzyme Immunoassay Tests for Anti-HCV: Components and Performance Characteristics**

Version of Test (manufacturer)	Peptides	Sensitivity*	Specificity*
1.0 (Ortho Clinical Diagnostics)	C100	81%	>99.4%
2.0 (Abbott Laboratories)	HC34 (c22), HC31 (c33), c100	85.7%†	99.83%

‡Includes c33 and c100 sequences.

automated platforms are available elsewhere in the world and are soon expected to be licensed in the United States. Most diagnostic reagents are defined as devices, but those that are used in the preparation of blood and blood products are required to meet the more stringent biologics requirements, because blood itself is defined as a biologic.

The sensitivity of these tests was defined in trials using patients diagnosed with NANBH. Because this diagnosis is not specific, the significance of the sensitivity figures is unclear. Of more importance now, at least in the context of blood donor screening, is the ability of the test method to detect infection at the earliest possible time during the seroconversion period. Studies of seroconversion panels suggest that currently available tests detect antibodies, on average, 70 to 80 days after exposure to the source of infection and 40 to 60 days after the initial detection of HCV RNA in the plasma. In addition, it should be noted that earlier versions of the EIA tests clearly failed to detect some infected individuals.[38] This is not surprising, because only a very limited number of viral epitopes were included in the capture reagent. Current tests for anti-HCV are whole-antibody assays. No tests are yet available for specific detection of immunoglobulin M anti-HCV.

Although these EIA tests have high sensitivity and specificity, there is a possibility that some reactive test results are nonspecific. When the EIA is used to screen blood donors, its actual positive predictive value is 70% to 80%.[36] Consequently, it is recommended that all asymptomatic individuals who test as reactive on EIA repeatedly should be further tested with an additional, more specific procedure. Currently, only one such immunologic method is licensed and available in the United States. This is a strip immunoblot assay (RIBA 3.0) that is constructed by application of recombinant or synthetic viral peptides representing c22, c33, c100, 5-1-1, and NS5 regions to nitrocellulose strips in a fixed pattern. The c-100 and 5-1-1 peptides are present in the same band on the strip. The expression carrier protein for the recombinant viral antigens is also applied (superoxide dismutase, SOD), as are strong and weak positive controls. Patient or donor samples are added to the strips and, after washing, adherent antibodies are detected by an appropriate enzyme-conjugated antiglobulin and visualization reaction. The number and intensity of bands are scored, and the result is interpreted as follows:

- *Positive:* Two or more bands with an intensity equal to, or greater than, that of the weak positive control band, plus nonreactive SOD band.
- *Negative:* No band with a greater intensity than the weak positive control.
- *Indeterminate:* Only one band reactive or any pattern in association with a reactive SOD band.

Table 44–2 summarizes the results of testing a large number of volunteer blood donations with HCV EIA and SIAs.

Unlike the situation with HIV, there does not seem to be a common pattern for the sequence of appearance of reactive bands in the blot during seroconversion with HCV. However, a number of studies have defined the relationship between particular bands, or band patterns, and the likelihood that a sample will also contain detectable HCV RNA. For example, Dow and colleagues[35] reviewed data from 177 blood donor specimens that were reactive on EIA and tested positive on the version 3.0 SIA. Among 82 samples with four positive bands, 69 (84.1%) were RNA-positive. Of the 54 samples with three positive bands, 40 (74.1%) were RNA-positive, whereas only 14 (34.1%) of the 41 samples with two positive bands were RNA-positive. Among the samples with indeterminate SIA results, the frequencies of RNA-positive results were 3 of 154 for c22, 1 of 220 for c33, 1 of 191 for c100, and 0 of 380 for NS5.[35] Thus, a few of the indeterminate patterns may be associated with the presence of RNA and, therefore, of active HCV infection. Similar data were published by Dodd and Stramer.[36]

TESTS FOR HCV RNA

Tests for HCV RNA serve an important role in diagnosis and patient management.[9,39] A variety of procedures is available, all of which depend on nucleic acid amplification, with one exception. The reverse transcriptase polymerase chain reaction (RT-PCR) is perhaps the most familiar. Viral RNA is reverse-transcribed to DNA, and two primers are used to define a sequence for repetitive amplification using a temperature-resistant DNA polymerase and a temperature-cycling protocol. A variety of methods may be used to detect the resulting amplified sequence, including visualization in gels, hybridization with labeled probes, and detection of amplicons in real time. Both qualitative and quantitative procedures are available.[5,40,41] In most cases, a conserved segment of the 5′ untranslated region of the genome is selected for amplification. PCR-based assays are available commercially (e.g., Roche Molecular Systems) as well as from independent reference laboratories; alternatively, they may be developed in-house with the use of standard technologies.

Another technique, known as nucleic acid sequence–based amplification (NASBA; a proprietary technology from Organon-Technika),[42] and the very similar transcription-mediated amplification (TMA; a proprietary technology from Gen-Probe Inc.) can be performed without temperature cycling. Two enzymes are used to produce an RNA amplicon, which can be detected by a variety of methods, including the hybridization protection assay. It should be noted that Chiron owns patent rights to the HCV genomic sequence used for amplification.

Sample collection, stability, and preparation for amplification are all important and must be properly controlled. HCV RNA is quite labile, and it is preferable, if not essential, to collect specimens in EDTA. Samples should be maintained at refrigerated temperatures and tested with minimal delay. A number of different methods may be used to prepare the RNA for testing, including conventional extraction from ultracentrifugal pellets, extraction on silica, and probe-capture techniques.

Finally, in a method known as the branched-chain DNA assay (B-DNA), a probe is labeled with a large branched DNA molecule that carries many copies of the detection label. This method does not amplify the target nucleic acid; rather, it provides a system in which numerous label molecules may be associated with a single target sequence. As might be expected, this technique is not as sensitive as amplification. However, the lack of sensitivity can be exploited to differentiate those patients with high levels of circulating RNA.[43,44]

Within the United States, almost all blood donations have been tested for HCV RNA since 1999.[34] Two methods are in use, RT-PCR(Roche) and TMA (Chiron/Gen-Probe). To date, all such testing has been performed on small pools of plasma samples, with current pool sizes of 24 for the Roche procedure and 16 for the Chiron/Gen-Probe method. Both tests have been licensed for routine use by the FDA and both have an analytical sensitivity of 12 or fewer copies of RNA/mL by probit analysis and a 95% detection level of 30 to 60 copies/mL. The overall sensitivity of the testing is, of course, proportionately reduced in pooled testing.

A number of methods are available for the determination of genotype and subtype. Not all methods are able to discriminate every genotype or subtype, however. Available methods may be broadly separated into those that depend on immunologic differentiation and those that directly detect variation in nucleic acid sequences. In the former case, specific peptides derived from the NS4 region are used to probe for antibodies in the specimen. Nucleic acid–based techniques include sequencing amplicons from selected genomic areas, PCR using genome-specific primers, DNA-enzyme immunoassay (DEIA), restriction fragment length polymorphism (RFLP) analysis of amplicons, and differential hybridization of amplicons with specific probes. Two of these approaches are commercially available (GEN-ETI-K DEIA kit and INNO-LiPA HCVI and HCV II). The reader is referred elsewhere for further details.[23,45]

Relatively little information is available about the impact of HCV genotype on the sensitivity of diagnostic tests, and some data suggest little variation in the analytic sensitivity of NAT.[46] However, a recent publication reviewing the performance characteristics of numerous blood screening assays for HCV antibodies suggests that most tests are not seriously impacted by genotype variations (El-Nageh, in press).

DIAGNOSTIC ALGORITHM

The Centers for Disease Control and Prevention (CDC) has published an algorithm for diagnostic testing for HCV among asymptomatic individuals (Fig. 44–1).[14] This algorithm is somewhat different from that recommended for blood donor screening, in that it explicitly permits the use of NAT to confirm a repeatedly reactive EIA result. However, NAT-negative samples must be further evaluated by an SIA. This algorithm also provides useful guidance in the context of treatment, but a more comprehensive guide to treatment was published in 2004.[9] Given that blood donors are now routinely evaluated by NAT for HCV RNA, it is hoped that these results may be incorporated into the notification and management of seropositive donors.[37,45]

IMPACT OF BLOOD DONOR SCREENING AND TESTING FOR HCV

Results of Testing

In 2001, the frequency of positive results among first-time blood donations as defined by RIBA was 0.3%, which is about one fifth of the national prevalence rate of 1800 per 100,000. The incidence of new infections in the donor population is 1.9 new infections per 100,000 person-years; the corresponding national incidence figure is 13.4 per 100,000 person-years.[47] Thus, the donor rate is about one fifth of the national rate. These differences are attributable, at least in part, to the procedures used to recruit safer populations for donation and to the measures used to question presenting donors about their medical and behavioral histories. However, it should be

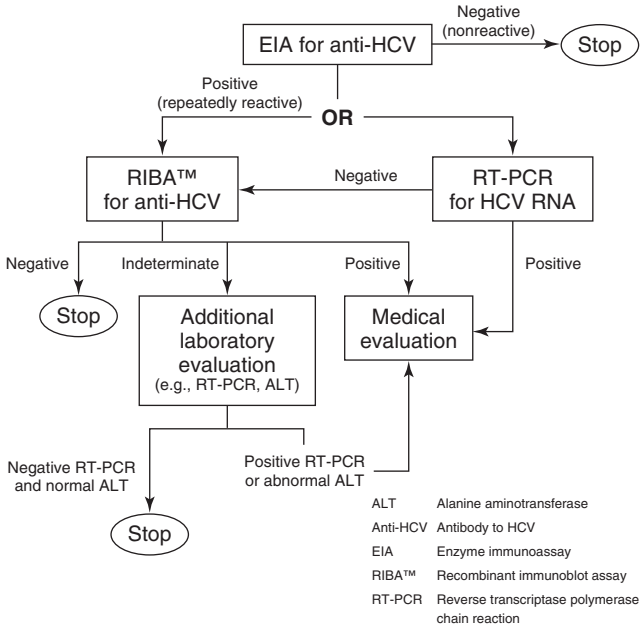

Figure 44–1 Algorithm for hepatitis C virus (HCV) testing among asymptomatic individuals. (From Centers for Disease Control and Prevention: Recommendations for prevention and control of hepatitis C virus (HCV) infection and HCV-related chronic disease. MMWR Morb Mortal Wkly Rep 1998;487[RR-19]:1–39.)

noted that only a very few donors are actually deferred on the basis of their response to risk questions, in part because donors do not always provide complete answers[48] but also perhaps because potential donors make a conscious decision to avoid giving blood so as not to have to answer the questions.

Risk of Post-transfusion HCV Infection

It is clear from a number of published studies that donor screening and testing measures have had a profound impact on the incidence of post-transfusion hepatitis C. Indeed, prospective studies have not demonstrated any infections since the implementation of the so-called multi-antigen tests for antibodies to HCV. But there is also substantial evidence for the efficacy of a variety of screening approaches used even before this time. The essentially complete elimination of commercial donation of whole blood had a major effect on reducing the frequency of post-transfusion hepatitis. It is also believed that a further reduction was seen as a result of more stringent donor questioning to reduce the risk of transmission of HIV and acquired immunodeficiency syndrome (AIDS), although subsequent information implies that the major effect would have come from a reduction in the number of injection drug users.

The first study to clearly demonstrate the impact of testing measures on hepatitis C infection was published by Nelson and colleagues.[49] They evaluated samples from a large population of patients undergoing cardiac surgery, using the first-generation test for anti-HCV. These researchers found that the risk of infection was 0.45% per unit prior to the implementation of any testing. After implementation of testing for ALT and anti-HBc, the rate of infection dropped to 0.19%. Finally, once the version 1.0 EIA test was implemented, the rate dropped to 1 per 3300 units (0.03%), a reduction of 84%.[49] A subsequent reevaluation using the more sensitive version 2.0 test on the blood recipients suggested that the actual risk was closer to 1:1700.[50] Once the version 2.0 test was introduced for blood donor screening, however, the frequency of residual infection declined profoundly. As pointed out previously, cases of hepatitis C were no longer observed in prospective studies, and risk estimates then had to be developed on the basis of the length of the window period (as determined from post-transfusion infections) and the incidence of new infections within the donor population. In a landmark publication in 1996, Schreiber and colleagues estimated the residual risk of HCV infection at 1 per 103,000 donations, based on a window period of 82 days and an incidence rate of 4.84 per 100,000 person-years.[51] Subsequent evaluations account for a 12- to 13-day reduction in the window period attendant on the implementation of the version 3.0 EIA and an overall decline in the incidence of HCV infection to 2.09 per 100,000 person-years. The latter figure translated to a residual risk of 1:276,000 repeat donations. The addition of HCV NAT was estimated to markedly reduce this risk to 1:1.935 million repeat donations. In the same paper, it was observed, on the basis of the results of NAT, that the incidence of HCV infections was 2.4 times higher among first-time donors.[52] Allowing for a 23% frequency of first-time donors in the Red Cross system, this translated to an overall risk of 1:1.39 million donations.[3] The relative stability of the detection rates for HCV RNA and the lack of change in prevalence rates for HCV antibody[53] suggest that this risk is not changing significantly, at least through the end of 2003.

It is interesting to speculate about the higher incidence of infections among first-time donors, but there are no definitive data. One possibility is that there are more test-seekers among people presenting to donate for the first time, although this is not necessarily supported by published data on interviews of RNA NAT-positive donors, because both first-time and repeat donors were found to be positive and to acknowledge risk factors for infection.[17] It is also possible that the process of giving blood has an educational impact and that individuals who learn about risk factors for bloodborne infections defer themselves from future donation.

Finally, it should be noted that there are cases in which HCV has been transmitted by blood units that have been fully tested for HCV, even after the implementation of NAT.[54] Such cases have usually been detected as a result of lookback and are too few to offer any quantitative estimate of residual risk. Window-period theory would strongly suggest that such cases would occur, and this is supported by the detection of HCV RNA in window-period samples, using ultrasensitive test methods. It is of interest to speculate on the minimal infectious dose of HCV. Busch has developed models based on the conservative assumption that it is as low as one genome equivalent per 20 mL of plasma. Using this assumption and back-calculating, the theoretical window period from the observed doubling rate of HCV plasma RNA during early infection has led to estimates that are largely compatible with currently accepted window period estimates.[55]

LOOKBACK

A positive test result for HCV antibodies does not provide any information about the duration of infection, even if accompanied by a positive finding for HCV RNA. Consequently, if a blood donor is found to be HCV antibody positive, it is possible that prior donations from that individual were infectious for HCV. This could occur by two broad mechanisms. First, a previous donation could have been made in the infectious but seronegative window period. Second, the prior donations could have been collected at a time when a less sensitive test was in use or even before testing was initiated. Accordingly, a focused lookback program has been initiated to locate, notify, test, and, if appropriate, treat recipients of such potentially infectious prior donations. Studies in Canada and elsewhere suggest that up to 70% of such recipients may indeed have been infected.[56,57] However, in the United States, the effort appears to have been less productive.

A team from the CDC reported that an estimated 98,484 blood components were identified as potentially infectious.[58] Of these, 85% had been transfused. This interim study found that lookback had been completed for 80% of the transfused products; 69% of the recipients had died. Of those living, 78% were successfully notified that they had received a potentially infectious blood component. It was estimated that, of recipients notified, 49.5% were tested for anti-HCV; of those, 18.9% were seropositive, but 32% of these individuals were already aware that they were seropositive. Thus, at the time of publication of the study, it was estimated just over 1000 individuals were newly notified of unexpected HCV infection; this estimate translated to a national figure of 1520, on the

assumption that the lookback process was to be completed. The figure represents fewer than 1% of all individuals who may have been infected as a result of transfusion.[58] It should be noted that this component of the lookback program was restricted only to donations that were identified as a result of testing with multi-antigen tests (i.e., versions 2.0 or 3.0). It is likely that, as lookback is extended to cover donors initially identified by the version 1.0 test, the proportional yield will be greater, but the efficiency of the process will certainly be affected by availability of required records.

On the other hand, the essential completion of achievable lookback affecting recipients of blood donated prior to the implementation of testing means that almost all available cases now represent lookback from incident cases of HCV infection. The yield of this aspect of lookback is now extremely low, and such yield will be further reduced as the impact of NAT is manifested. The ethical imperatives for lookback continue, but the public health benefits of this process are becoming vanishingly small.

COMMENT AND SUMMARY

In its way, the history of hepatitis C has been as remarkable as that of HIV and AIDS. In retrospect, hepatitis C was the blood-borne agent most commonly transmitted by transfusion in the United States, right up until the early 1990s. The legacy of this problem will be seen for many years, as the long-term health consequences of HCV infection become manifest. The almost complete elimination of the problem of transfusion-transmitted HCV is the result of many years of dedicated study of an intractable problem. There were no simple solutions; the virus was refractory to laboratory study, and there was a truly frustrating inability to identify any serologic markers of infection. Indeed, only at the very end of the 20th century was a naturally occurring, circulating viral antigen recognized and then only in the few weeks preceding seroconversion.

As with HIV, the first laboratory approach to abrogating transfusion-transmitted HCV infection was the development of serologic tests. In the case of HCV, however, this development was achieved through the combination of years of study of the disease, development of animal models, and the painstaking application of new recombinant technology. It is fitting that Harvey Alter and Michael Houghton received the 2000 Lasker award for this work, but hundreds of others contributed over many years.

Serologic and nucleic acid testing have essentially eliminated the risk of transfusion-transmitted HCV. Plasma derivatives are prepared from highly tested starting material and are further treated with advanced inactivation procedures. It is of interest to note, however, that whereas the early tests removed a substantial fraction of antibody-positive units, they failed to identify all infectious units, probably leading to the unexpected occurrence of HCV in recipients of some immunoglobulin products.

Despite the success of testing for HCV, there continue to be barriers to other aspects of management of this virus. As with many viral diseases, treatment options for HCV are limited and incomplete. More baffling, however, are the difficulties inherent in understanding and manipulating the interactions between the immune system and HCV. Development of an effective vaccine seems to be a particularly elusive goal.

Chapter 45

HIV, HTLV, and Other Retroviruses

Eberhard W. Fiebig • Edward L. Murphy • Michael P. Busch

This chapter provides a general overview of retroviruses, with emphasis on those aspects of human retrovirus epidemiology, pathophysiology, and detection of greatest relevance to specialists in transfusion medicine. The four major known pathogenic human retroviruses—human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2) and human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2) are considered in detail. Strategies to further reduce the risk of retrovirus transfusion transmission are addressed.

DEFINITION, LIFE CYCLE, AND DISTRIBUTION OF RETROVIRUSES

Retroviruses were among the first viruses described in the scientific literature. They constitute a major class of membrane-coated, diploid, single-stranded RNA viruses with wide distribution in nature; examples exist in genera ranging from insects to reptiles to virtually all mammals.[1] The human retroviruses HIV and HTLV belong to the lentivirus and oncornavirus groups of the retrovirus family, respectively.[2] Characteristic features of retroviruses are a distinct genomic organization, the presence of viral particle (virion)-associated reverse transcriptase, and a unique replication cycle (Fig. 45–1).

The first step of infection is attachment of virus particles to the cell membrane. In the case of HIV, which has tropism for T cells and macrophages, virus glycoprotein 120 (gp120) attaches to CD4 molecules expressed on the surface of these cells. Efficient infection also requires engagement of viral proteins with chemokine coreceptors, identified as CCR5 on macrophages and CXCR4 on T cells.[3] After entry into a host cell, typically by fusion of the virion and host cell membranes, the reverse transcriptase enzyme copies viral RNA into complementary double-stranded DNA (cDNA). Virion-associated integrase then mediates integration of this cDNA into random sites in the host cell's genome, forming integrated viral cDNAs termed *proviruses.* Subsequent transcription, processing, and translation of viral genes are mediated principally by host cell enzymes, although both viral and host cell regulatory gene products influence the level and pattern of viral gene expression and replication. The classic retrovirus life cycle is completed when nascent particles associate and bud from the plasma membrane to form progeny virions, which can then infect other cells and other organisms.

Retroviruses can also spread horizontally, by fusion of infected and uninfected cells, or vertically, by replication of integrated viral DNA along with cellular DNA during mitosis or meiosis. Indeed, integrated proviruses have evolved that are passed congenitally through the germline; these so-called *endogenous retroviral elements* (as contrasted with vertically transmitted exogenous retroviruses) are present in many species, including humans, and in some species account for up to 10% of total genomic DNA.[2]

Disease manifestations of retroviruses are highly variable. Many animal species harbor exogenous or endogenous retroviruses that appear to be benign and may in fact be beneficial in restricting infection by related pathogenic retroviruses. On the other hand, retroviruses became the focus of intense research in the 1960s and 1970s because of their capacity to induce malignancies in a wide range of species. The demonstration that certain retroviruses (termed *acute RNA tumor viruses*) rapidly transform target cells in vitro and induce tumors within days to weeks of inoculation into animals greatly facilitated experimental investigation of viral carcinogenesis.[4] Studies of the molecular differences between these acute retroviruses and genetically related *slow viruses* (which failed to transform cells in vitro and only occasionally caused tumors many months after inoculation) led to the discovery of viral oncogenes, which were responsible for tumorigenesis. This achievement was followed by the revolutionary discovery that these viral oncogenes had in fact arisen by recombination events between slow viruses and key cellular genes termed *proto-oncogenes.*[4] Thus, investigation of retrovirus-induced cancers in animals led to unparalleled insights into normal cell biology and disease pathogenesis in humans. Retroviruses have also attracted interest from researchers who explore nonpathogenic strains as vehicles for therapeutic gene transfer.

DISCOVERY OF HUMAN RETROVIRUSES

The first report of successful isolation and characterization of a bona fide human retrovirus (later termed *HTLV-1*) occurred in 1980 and involved a patient with a rare type of leukemia (now called *adult T-cell leukemia/lymphoma* [ATL]).[5] Subsequently, HTLV-1 was also identified as the cause of a rare neurologic condition known as *HTLV-associated myelopathy/tropical spastic paraparesis* (HAM/TSP).[6] A second, closely related human retrovirus (HTLV-2) was isolated in 1982 from a patient with a somewhat more common type of leukemia (hairy cell leukemia)[7]; further surveys failed to show a relationship between HTLV-2 and hairy cell leukemia, but established the virus as a causative agent of HAM/TSP.[6,8] Both HTLV-1 and HTLV-2 are thought to be derived from simian T-lymphotropic retroviruses transmitted to humans over the past hundreds to thousands of years.

The full pathogenic potential of human retroviruses was not realized until HIV was established as the cause of

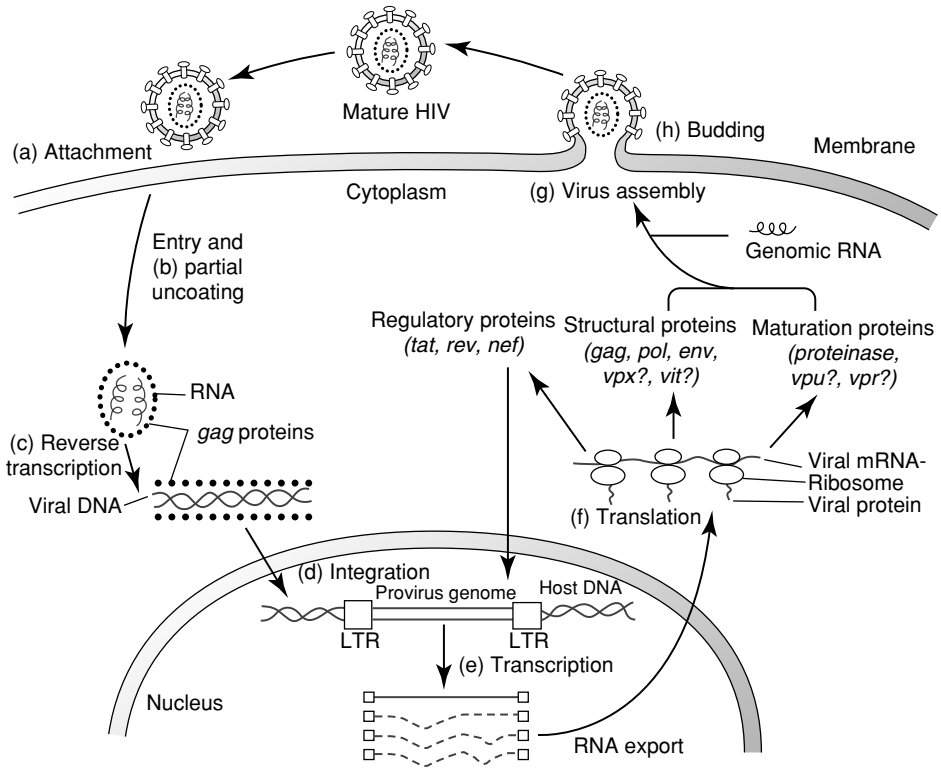

Figure 45–1 Replication cycle of human immunodeficiency virus type 1. (a) After attachment of virus particles to the CD4 receptor molecule, virus enters the cell by a pH-dependent mechanism and/or endocytosis. Not shown is the required interaction of viral proteins and chemokine co-receptors. (b) The outer lipid envelope of the virus is removed when the particle undergoes fusion with cytoplasmic vacuoles. (c) The core particle that remains is the site for reverse transcription of the virion RNA into DNA. (d) After translocation into the nucleus, integration into the DNA of the cell occurs. (e) The integrated provirus genome is transcribed by cellular RNA polymerase II. (f) Translation of viral messenger mRNA produces regulatory proteins, which stimulate synthesis of maturation proteins and the structural proteins of the virion. AIDS in 1984. It is now thought that the virus originated in nonhuman primate species and was introduced into native people of the central African rain forest.[9] There may have been multiple introductions of the virus into humans dating back several centuries (based on phylogenetic *molecular clock* analyses); so far, however, the earliest documented evidence of HIV infection in humans comes from a blood sample collected in 1959.[10] Sub-Saharan Africa remains the area worst affected by the epidemic today, with an estimated 60% of the global caseload.[11] According to World Health Organization figures, 4.1 million people were newly infected in 2005, raising the projected number of infected people to a staggering 38.6 million worldwide.[11]

HUMAN IMMUNODEFICIENCY VIRUS

Genomic Organization and Virion Structure

The organization of the HIV RNA genome is shown in Figure 45–2. The products of the *gag*, *pol*, and *env* genes that are shared among all retroviruses give rise to the structural elements of the virion, which is shown in Figure 45–3. Similar to other lentiviruses, HIV contains at least six additional genes, which encode for regulatory proteins and virulence factors that appear to play an important role in pathogenicity. Detection of specific antibodies against viral proteins or identification of viral nucleic acid sequences in infected hosts provides the basis for screening and supplemental assays used in blood donor eligibility testing.

HIV Diversity: HIV-1 Subtypes and HIV-2

Extensive genetic diversity is a hallmark of HIV and other lentiviruses. A contributing factor is the high error rate during reverse transcription, which has been attributed to the negligible proofreading exonuclease activity of the reverse transcriptase.[12] Nucleotide misincorporations may occur at an astonishingly high rate of 5 to 10 per HIV genome per replication cycle, a phenomenon known as *hypermutation*. Insertions, deletions, and intergenic recombination add to the trend toward genetic diversification.[13] Within an HIV-1–infected individual, a swarm of "quasispecies," or HIV variants, develops over time,[14] and dual and multiple infections with recombination between the infecting HIV-1 strains have been reported.[15,16]

On the basis of relatedness of genomic sequences, the HIV-1 family is divided into main (M), outlier (O), and non-M, non-O (N) groups, with 11 distinct subtypes or clades (A through K) recognized within group M.[17] Of note is the currently almost exclusive prevalence of clade B strains in the United States and, to a lesser degree, Europe; other clades are more predominant in South America and Asia. The greatest genetic diversity of HIV-1 strains is found in central Africa, in keeping with this area's role as the presumed point of origin of the pandemic. The worldwide distribution of HIV-1 and -2 subgroups and clades is depicted in Figure 45–4. A recent survey of 292 U.S. blood donors detected by anti-HIV-1/HIV-2 screening in the late 1990s identified only 7 (2.3%) non-B subtypes, which nonetheless reflects a trend toward increasing diversity relative to earlier periods (e.g., 3 [0.8%] of 383 donors from 1993 through 1996).[18] This is a concern because the seroconversion window period from beginning of infectiousness to detectability of anti-HIV is prolonged with non-B strains when testing is performed with assays in routine use for blood donor screening in the United States, which are optimized for subtype B detection.[18]

Group O viral strains are most common in Cameroon and surrounding West African countries, where an estimated 1% to 2% of HIV infections are caused by these viral strains.[19,20]

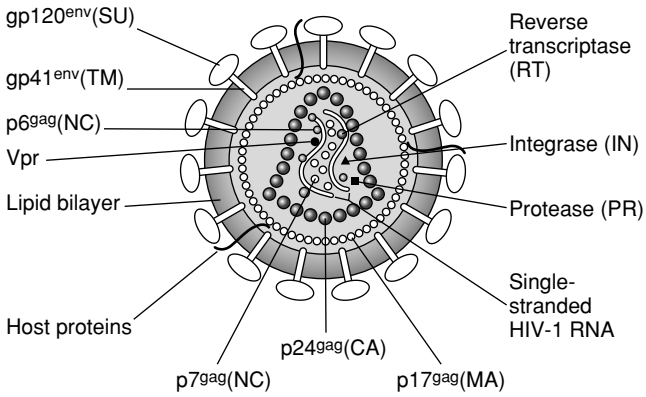

Figure 45–3 Schematic of the HIV-1 virion. Each of the virion proteins making up the envelope (gp120env and gp41env) and inner core (p24gag, p17gag, p7gag, and p6gag) is identified. In addition, the diploid RNA genome is shown associated with reverse transcriptase (RT), an RNA- and DNA-dependent DNA polymerase. Integrase (IN) and protease (PR) are also found in the mature HIV-1 virion. The auxiliary protein Vpr is incorporated into the HIV-1 virion through an interaction with the p6gag protein, which comprises the carboxyl terminus of the p55gag precursor protein. CA, capsid protein; MA, matrix protein; NC, nucleocapsid protein; SU, surface protein; TM, transmembrane protein. (Reproduced with permission from Geleziunas R, Greene WC. Molecular insights into HIV-1 infection and pathogenesis. In Sande MA, Volberding PA (eds). The Medical Management of AIDS, 6th ed. Philadelphia, WB Saunders, 1999, p 25.)

Outside this geographic area, group O isolates have rarely been seen. The current risk of HIV-1 group O infection in the United States is very low. Only two such infections have been reported; both involved immigrants from West Africa who had never donated blood or plasma. Furthermore, surveillance testing for HIV-1 divergent strains did not detect any group O viral isolates among 1072 serum samples from high- and low-risk population groups in the United States and Puerto Rico.[21] Nonetheless, concern arose in the mid-1990s when studies demonstrated that some group O isolates were not reliably detected by a number of HIV-1 and HIV-1/HIV-2 combination assays,[22] including some that are used for blood donor screening.[23] Antibody assays employing synthetic peptides or recombinant antigens on the solid phase, and those using the so-called *third-generation antigen-sandwich format*, were especially prone to false-negative results. Since then, test manufacturers have moved quickly to enhance their assays' sensitivity to unusual variants such as subtype O. As an added precaution, the U.S. Food and Drug Administration (FDA) continues to recommend permanent deferral of blood and plasma donors who were born, resided, or traveled in West Africa since 1977 or had sexual contact with someone identified by these criteria.[24]

HIV-2, discovered in 1985 in several countries in West Africa,[25] was initially called HTLV-4 and lymphadenopathy-associated virus type 2. Although still primarily concentrated in West Africa, HIV-2 has now spread throughout Western Europe, where a substantial number of infected blood donors have been detected, and cases of transfusion transmission have been documented.[26] HIV-2 is transmitted in the same manner as HIV-1 (i.e., by sexual contact, intravenous drug use, and, at a lower rate than for HIV-l, from mother to child) and causes progressive immunodeficiency, with susceptibility to an array of opportunistic infections similar to those seen with HIV-1. Rates of disease progression and secondary viral transmission appear to be lower, however, in persons infected with HIV-2 than in those infected with HIV-1, possibly owing to lower viral burden in HIV-2 infection.[27,28]

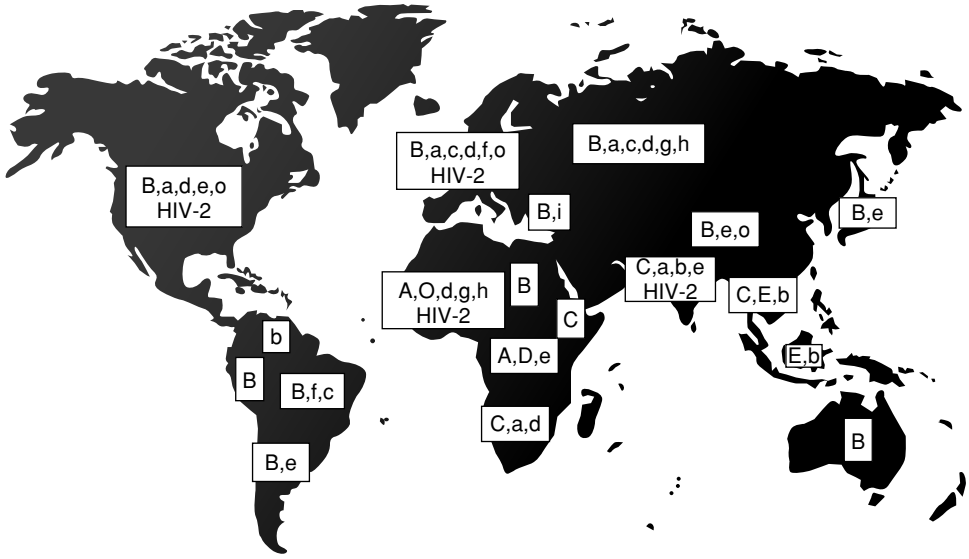

Figure 45–4 Distribution of human immunodeficiency virus (HIV) throughout the world according to the prevalence of its types and subtypes (clades). The distribution of HIV-1 clades is indicated by letters A to I (more prevalent in capital letters). Clades of HIV-2 are not shown separated. (Reproduced with permission from Diaz RS, Busch MP. Human immunodeficiency viruses. In Anderson KC, Ness PM (eds). Scientific Basis of Transfusion Medicine: Implications for Clinical Practice, 2nd ed. Philadelphia, WB Saunders, 2000, p 508.)

HIV-l and HIV-2 are highly (>50%) homologous at the nucleic acid sequence level, and they crossreact immunologically to a great extent (particularly the core and polymerase antigens). For this reason, up to 90% of sera from HIV-2–infected persons have been found to test positive with FDA-licensed anti-HIV-1 assays, with variable reactivity on HIV-1 Western blot analysis.[29,30] This crossreactivity undoubtedly prevented transfusion transmission of HIV-2 by blood screened for anti-HIV-1 in areas where the type 2 virus was present before implementation of combination HIV-1/HIV-2 screening tests. This high-level crossreactivity has also facilitated surveillance for HIV-2 in regions where it was rare or absent.[31,32] From 1987, when the first case of HIV-2 infection was diagnosed in the United States, to 1998, a total of 79 persons with HIV-2 infections were documented, of which approximately two thirds had been born in West Africa.[33]

Combination HIV-l/HIV-2 assays were developed in the late 1980s,[34–36] and mandatory implementation of either a combination test or a separate anti-HIV-2 test in the donor screening setting was required by the FDA effective June 1, 1992.[37] From the implementation of HIV-2 screening in 1992 through 1996, three prospective U.S. blood donors were found to be HIV-2 positive at the time of attempted donation.[38] One was a U.S.-born woman without identifiable risks for HIV infection; the other two were men, born in France and Liberia, West Africa respectively, who had resided for years in West Africa. These three cases of HIV-2 infection were detected from screening of more than 50 million whole blood donations, indicating that the prevalence of HIV-2 is very low (less than 1 in 15 million screened donations). A more recent study identified a single HIV-2–infected donor among 7.2 million donations at 18 U.S. blood centers from 1997 through mid-2000.[18] As of 2001, no cases of HIV-2–infected transfusion recipients had been reported in the United States.

Clinical HIV-1 Disease

In approximately 60% of acute HIV infections newly infected persons experience a nonspecific flulike illness, usually within 2 to 4 weeks of exposure.[39] This *retroviral syndrome* coincides with appearance of antibody to HIV antigens and is thought to represent a reaction of the immune system to the rapidly proliferating virus. In most cases signs and symptoms of acute HIV disease subside within weeks to a few months, giving way to a clinically silent period that can last several years. The lack of clinical symptoms during this stage of the disease is deceptive, however, because viremia persists in untreated infection and the number of CD4+ lymphocytes, the primary target of HIV, is gradually declining.[40] Paralleling the loss of CD4+ lymphocytes are clinical disease manifestations, such as opportunistic infections, numerous conditions related to suppression and dysfunction of the immune system, direct viral effects on multiple organ systems, and ultimately death after a median survival of 8 to 10 years from exposure. Although it appeared initially that disease manifestations and clinical course of transfusion-transmitted HIV infection follows a more rapid course than HIV infection due to other routes of transmission, subsequent analysis did not confirm this impression.[40]

Also not confirmed were concerns that allogeneic transfusions—via immune stimulation by donor leukocytes—may result in accelerated disease progression and shortened survival in HIV-infected transfusion recipients. The Viral Activation by Transfusion Study (VATS), a large multicenter U.S. clinical trial, specifically addressed this issue and found no evidence of significant activation of HIV replication or accelerated disease progression in HIV-1–infected recipients of either leukoreduced or nonleukoreduced transfusions.[41]

Widespread availability of potent antiretroviral therapy in western countries since the late 1990s has changed the course of HIV disease to that of a manageable chronic condition with reduction in opportunistic infections and other HIV-related complications and has markedly prolonged survival. Unfortunately, current treatment regimens are not capable of eradicating HIV from cell- and tissue-based sanctuaries throughout the body, and therapy-related side effects and development of resistant viral strains add to the problems of managing HIV-infected patients.[42]

Efficiency of HIV Transmission by Blood and Blood Products and Transmission Risk Prior to Blood Donor Screening

Human immunodeficiency virus is sensitive to drying[43] but survives refrigeration of blood and freezing of plasma. Virus

present in the bloodstream of an undetected infected donor is therefore readily passed on by transfusion. Data from the Transfusion Safety Study (TSS), which traced and enrolled recipients of retrospectively identified HIV-1–seropositive units,[44,45] demonstrated HIV transmission in 111 of 124 (89.5%) enrolled recipients.[45] Neither characteristics of the donor's infection nor inherent recipient susceptibility factors significantly influenced transmission of HIV-1 by transfusions.[46] Variables that have been identified to correlate with likelihood of HIV-1 transmission are the type of blood component transfused and its duration of storage.[46,47] Washed red blood cell (RBC) units and RBC units stored more than 26 days had lower transmission rates than other components. This observation, as well as experimental evidence,[48] suggests that component manipulations that reduce the number of viable leukocytes, free virus, or both may reduce but not eliminate infectiousness.

With regard to recipients of clotting factor concentrates, an average of approximately 50% of hemophiliacs treated with factor VIII in the early 1980s experienced seroconversion.[49,50] However, the rate of seroconversion to anti-HIV-l positivity in hemophiliacs who were treated with very high doses of factor VIII (>500,000 units) approached 100%.[49] This finding indicates that, perhaps with the rare exception of persons lacking HIV-1 co-receptors required for infection,[51] virtually no one is resistant to HIV-1 infection, given a large enough inoculum and repeated exposures.

Given the high efficiency of HIV transmission by intravenous administration of infected blood and blood products, it is not surprising that the majority of HIV transmissions in the United States occurred before discovery of the virus and institution of blood donor screening. A principal lesson learned from the HIV-1 epidemic is how an infectious agent with a prolonged interval between infection and manifestation of clinical disease can spread silently within a population (and its blood donor base) for years before recognition.[52] In the United States, this early phase was localized primarily to homosexual and bisexual men, groups who were eligible blood donors at the time. Although we know now that the virus began to spread at an exponential rate in these men in the late 1970s, it was not until 1981 that clusters of Kaposi sarcoma and *Pneumocystis* pneumonia were first recognized among homosexual men in New York and Los Angeles. In late 1982, descriptions of AIDS-like illnesses in hemophiliacs and recipients of blood components first appeared.[53,54] With these reports, a blood-borne infectious etiology for AIDS became probable, and efforts were initiated to exclude from blood donation persons with symptoms of or risk factors associated with AIDS.[55] Approximately a year later, HIV-1 was discovered,[56] an event soon followed by development of diagnostic anti-HIV-1 tests, which were licensed for donor screening in March 1985.

Epidemiologic evidence showed that the risk of transfusion-associated HIV-1 infection in the San Francisco Bay Area, one of the epicenters of the early HIV epidemic in the United States, rose rapidly from its first occurrence in 1978 to a peak risk of approximately 1.1% per transfused unit in late 1982 (Fig. 45–5). Beginning in early 1983 and continuing through implementation of anti-HIV-1 screening, there was a marked, progressive decline in risk as a result of diminishing numbers of blood donations from at-risk or infected individuals. This decline was directly attributable to growing awareness of the infectious nature of AIDS in the homosexual community and to implementation and refinement of

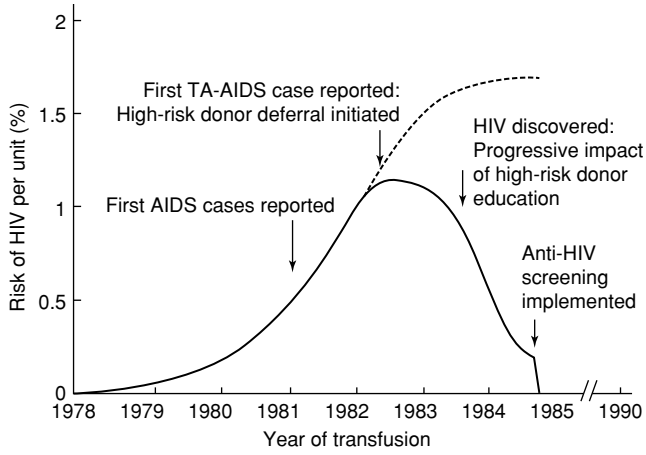

Figure 45–5 Risk of human immunodeficiency virus (HIV-1) infections from transfusions in San Francisco before anti-HIV screening. *Solid line* represents estimated risk of recipient infection per unit transfused. *Dashed line* indicates what the risk would have been if high-risk donor deferral measures had not been implemented. The risk in the United States as a whole probably trailed that in San Francisco by approximately 1 year, and the peak risk was of lower magnitude. (Modified from Busch MP, Young MJ, et al. Risk of human immunodeficiency virus (HIV) transmission by blood transfusions prior to the implementation of HIV-1 antibody screening. Transfusion 1991;31:4-11.)

donor education and deferral measures by blood banks.[57,58] In fact, it was estimated that approximately 90% of high-risk men in San Francisco who were donors between 1980 and 1982 deferred themselves from blood donation before implementation of the anti-HIV-1 test in early 1985.[57] These data demonstrate the effectiveness of donor education and self-deferral measures. Despite successful interventions like these, it has been estimated that more than 12,000 transfusion recipients in the United States were infected with HIV from transfusions administered before implementation of blood donor screening for HIV infection.[59]

Hemophiliacs, who are exquisitely vulnerable to transfusion-transmitted diseases because of exposure to factor concentrates derived from plasma pooled from thousands of blood donors, were hit especially hard by the early epidemic of transfusion-transmitted AIDS.[50] Incidence and prevalence data from 1978 through 1990 for 16 hemophiliac cohorts in the United States and Europe show that infections began in 1978, peaked in October 1982 at 22 infections per 100 person-years at risk, and declined to 4 per 100 person-years by July 1984. Few new infections occurred among hemophiliacs after 1986, but by that time, 50% of subjects in the combined cohort were infected. The decline in incidence from the infection peak in late 1982 coincided with health interventions introduced to reduce transmission, including recommendations for reduction in use of factor concentrates in 1982, voluntary donor deferral in 1983, and the availability of heat-treated factor VIII in 1984 and of HIV-1 screening in 1985.

Blood Donor Testing for HIV-1 and HIV-2 Antibody

The development of a sensitive and specific test for antibodies to HIV that was suitable for diagnosis (with confirmation by immunoblot analysis) and large-scale screening[60] represented a major breakthrough in combating the evolving pandemic in the early 1980s. Mandatory screening of all blood, plasma, and platelet donor samples for HIV with the antibody test began in the United States shortly after the assay became commer-

cially available in March 1985.[61] Initial testing for antibodies to HIV-1 and HIV-2 is performed on serum or plasma from *pilot* tubes collected at the time of donation. If the initial test result is reactive, duplicate retesting is performed. If results of one or both second tests are reactive, the unit is designated *repeat reactive* and discarded. A process is also initiated to identify and quarantine all in-date components from any prior donations from that donor and to notify recipients who received blood components from prior donations.[62] Developments in test methodology have occurred at a rapid rate, and blood banks have implemented improved assays as soon as possible after FDA licensure. The evolution of antibody assays has been achieved through improvements in the antigens on the solid phase and in assay formats. From crude viral lysates, production moved to viral lysate assays spiked with purified HIV-1 antigens, and then on to the use of cloned (recombinant DNA [rDNA]-derived) and synthetic peptide antigens. Although concerns have been raised about the sensitivity of rDNA-derived and peptide antigen-based enzyme immunoassays (EIAs) to immunologically variant strains,[22,23] these assays have been "engineered" to include highly selected antigenic regions of HIV-1 and HIV-2 that maximize sensitivity to infected subjects from around the world. Consequently, rDNA-derived and synthetic peptide antigen-based assays are now in wide use in U.S. and non-U.S. blood banks.

Test manufacturers have also developed new assay formats with greater capacity to detect low-titer immunoglobulin M (IgM) antibody produced during early seroconversion. For example, the recombinant "antigen sandwich" EIA format allows use of lower dilutions of donor sera and detects IgM with better sensitivity.[34–36] The progressive introduction of assays with increased sensitivity to early infection has led to significant narrowing of the seroconversion window period and concomitant reductions in the HIV transmission risk associated with receiving screened blood.[63,64] The realization that HIV-1 subgroup and variant strains may not be reliably detected by current HIV-1/HIV-2 assays has led to demands by the FDA and efforts by kit manufacturers to reengineer standard assay formats to improve detection of unusual viral strains without compromising their sensitivity to main group HIV-1/HIV-2 strains.[65]

Testing for HIV Antigen

Testing of blood donor samples for HIV-1 antigens (in practice p24 antigen) was implemented in the United States in 1996 in addition to HIV antibody testing. This decision was based on studies showing that HIV-1 antigen appears in blood early in the course of infection, approximately 1 week before antibody is detectable. Transmission of HIV has been reported from transfusion of seronegative blood that was later shown to contain p24 antigen; the donors subsequently showed seroconversion.[66] Mathematical models, constructed with findings from geographic areas with very high incidence of new HIV infections, suggested that routine antigen testing would detect 1 antigen-positive/antibody-negative donation in every 1.6 million tested.[67] In reality, this projection was not achieved. Only seven donations from infected window-phase (p24 antigen-positive/anti-HIV-negative) volunteer donors were intercepted on the basis of p24 antigen testing alone in the first 5 years of screening, for an observed yield of 1 in 10 million donations.[68] A possible explanation for the underperformance of HIV-1 antigen testing in detecting HIV-1 antibody-negative window period infections is that prospective blood donors in the early phase of HIV-1 infection who have HIV-1 antigen only may be experiencing symptoms from acute retroviral infection that deter them from blood donation or result in their rejection during the predonation history and physical examination. After licensing of several nucleic acid amplification testing (NAT) assays suitable for blood and source plasma donor screening beginning in September 2001, the FDA allowed discontinuation of HIV-1 p24 antigen testing for blood donor samples screened by a licensed NAT assay.[69] In practice, this has resulted in virtual disappearance of p24 antigen testing from blood donor screening algorithms in the United States. However, antigen/antibody combination tests are employed in many developing countries where NAT screening is not feasible.

Nucleic Acid Testing

Detection of genomic HIV RNA sequences in plasma by NAT represents the most sensitive method for identification of newly infected persons who have not yet developed antibody to the virus (i.e., are in the preseroconversion window period of the infection).[70,71] An unrecognized new HIV infection in a healthy-appearing blood donor is by far the greatest single risk factor for transmission of the virus via transfusion,[72] development of suitable NAT assays for large-scale blood donor screening in the late 1990s was an important milestone toward the ultimate goal of complete prevention of HIV transmission from screened blood units. NAT assays began to be used in Europe for regional blood donor screening in 1997.[73] In the United States, routine testing of blood donor samples with combination NAT assays for HIV and hepatitis C virus (HCV) began in the spring of 1999 in the form of large-scale clinical trials conducted under investigational new drug (IND) applications to the FDA. Despite the research aspect, NAT quickly became the standard of practice, and by July 2001 essentially the entire U.S. blood supply was screened for HIV (and HCV) with the new technology. NAT is currently performed on pools of 16 to 24 blood donor samples, known as *minipool NAT*. The pooling strategy lowers the sensitivity of the test but allows faster turnaround times, which is critically important for on-time release of cellular blood components. In 3 years of practical experience in the United States from March 1999 to April 2002, HIV NAT detected 10 HIV-1 RNA-positive, HIV-1 EIA-negative, p24 antigen-negative donors out of 37 million donations tested (approximately 1 in 4 million) and missed no p24 antigen-positive, HIV-1 EIA-negative donations.[70] These results are consistent with a modest reduction in the infectious window period of HIV, averaging approximately 10 to 12 days against a sensitive HIV-1 antibody and 3 days against p24 antigen testing. Rare, unfortunate cases of HIV transmission from minipool NAT-screened units have occurred, demonstrating the potential infectiousness of such units.[62,74–77] The two NAT test systems for blood donor screening were licensed by the FDA in 2002, allowing facilities that incorporated licensed HIV NAT systems to discontinue HIV-1 antigen testing.

Supplemental Testing

Because of the exquisite sensitivity of HIV EIAs used in blood donor screening and the low pretest probability of HIV infection among low-risk blood donors, the majority of positive screening results are false positive, despite the excellent specificity of the tests. Supplemental assays are therefore

essential to confirm positive screening results before donor counseling. Supplemental testing must use FDA-licensed reagents and must rule out both HIV-1 and HIV-2 infection.[37] Although combination HIV-1/HIV-2 supplemental assays using rDNA-derived or synthetic peptide antigens that appear to accurately detect and discriminate anti-HIV-1 and anti-HIV-2 have been developed,[78] they have never been approved by the FDA. Therefore, current confirmatory algorithms in U.S. blood banks employ HIV-1 viral lysate-based Western blots or immunofluorescence assays, in combination with a licensed anti-HIV-2 EIA and an unlicensed HIV-2 supplemental assay.[37] Interpretive criteria for Western blots have evolved over time as tests have improved and our understanding of the meaning of various banding patterns has grown. For currently licensed assays, a positive interpretation requires antibody reactivity to two of the following three HIV antigens: p24 (the major gag protein), gp41 (transmembrane env protein), and gp120/160 (external env protein/env precursor protein). Although these criteria are generally accurate, it is clear that some donors who show antibody reactivity only to the envelope glycoproteins are not infected with HIV-1, resulting in false-positive classifications by Western blots.[79] It is important, therefore, that all initial positive Western blot results are confirmed by testing of a separate follow-up sample, both to rule out specimen mix-up or testing errors and to discriminate nonspecific patterns from early seroconversion. A *negative* test result by Western blot is, by definition, the absence of any bands. Any other pattern of reactivity that does not meet criteria for a positive result is classified as *indeterminate*. Only a very small proportion of donors who test indeterminate on Western blot are infected with HIV-1.[80] Holodniy and Busch[81] provide a detailed discussion of interpretive criteria and review of developments in HIV supplemental test technology.

Because HIV NAT testing results are now routinely available on essentially all U.S. blood donations, this information can provide valuable additional clues regarding the infectious status of a donor with inconclusive serologic HIV test results. Donors with true positive repeat reactive HIV EIA results are expected to be reactive on minipool NAT testing[82]; a negative NAT test result thus suggests a false-positive HIV EIA result. It should be noted, however, that NAT has not been approved for supplemental HIV testing and is not yet incorporated in official confirmatory testing algorithms.

Recipients of prior donations from donors with confirmed positive antibody or NAT results are traced in a process called *lookback*.[62,83] Seronegative donors whose supplemental test results are negative (or persistently indeterminate and NAT-negative) are eligible for possible reentry into the donor pool according to an FDA-specified protocol,[37] although in practice, logistical and legal considerations have generally prevented reinstatement of such donors.

Risk of Infection from Screened Donations

Implementation of anti-HIV-1 screening in 1985 resulted in a marked decline of virus transmission by transfusion over the first several years of screening.[84,85] However, initial hopes that the newly developed antibody test would lead to eradication of HIV transmission by blood donor screening were not fulfilled.

In the late 1980s, well-documented cases of HIV-1 transmission from screened blood transfusions were reported,[86] and 14 of 106 (13%) cases initially reported as due to infections from screened blood transfusions could be confirmed. It was therefore clear that a small number of transmissions continued, despite screening with antibody tests. After adjusting for uninvestigated cases, and assuming an equal distribution of infections from 1986 through 1991, investigators from the Centers for Disease Control and Prevention (CDC) estimated that during that period, approximately five transfusion-associated AIDS cases due to infections from anti-HIV-screened blood transfusions had occurred per year.[87]

In the United States, two prospective studies estimated the risk of HIV transmission from antibody-screened donations at approximately 1 in 60,000 units between 1985 and 1991.[88,89] These studies were discontinued in 1992 because of their high cost. Since then, an alternative approach has been developed for estimating the risk of HIV infection from transfusions, now known as the *incidence-window period model*.[67] It is based on the premise that the risk of viral transmission by blood transfusion in a given geographic area is primarily a function of the *incidence rate*—that is, the number of newly infected blood donors per person-years of observation—and the length of the *window period*—defined as the time from infectiousness to antibody seroconversion. This concept of a window period can also be applied to other HIV tests, such as p24 antigen test, HIV-1 RNA NAT, Western blot, and "detuned" HIV-1 antibody assays, where results with a sensitive antibody test are compared with a modified less sensitive assay to discriminate recent from well-established infections.[90]

Sequential emergence of assay reactivity allows classification of primary HIV-1 infection into distinct laboratory stages (Fig. 45–6).[82] Determination of the length of window periods associated with HIV-1 assays enables estimation of residual risk of HIV-1 transmission from repeat donors and, with some adjustments, from first-time donors. Window period estimates for HIV-1 antibody tests in use in the United States dropped from a median of 45 days (95% confidence interval, 34–55 days) for the overall period from 1985 to 1990 to approximately 22 to 25 days after routine introduction in 1992 of new format anti-HIV-1/HIV-2 combination tests, which detect HIV-specific IgM antibody 10 to 15 days earlier than previously available assays.[63.] By combining the 25-day window period estimate with data on the frequency of HIV seroconversions in large U.S. donor populations, two independent studies derived point estimates for the risk for HIV transmission during the period 1992 through 1995 as 1:450,000[91] and 1:495,000.[92] Introduction of HIV-1 antigen screening in 1995 further reduced the risk, but because fewer than expected HIV-1 antigen-positive HIV-1/2 antibody-negative units were intercepted once the test was introduced, the test's contribution to risk reduction seems to have been rather limited. In contrast, incorporation of minipool NAT into routine blood donor screening[93] was able to reduce the risk of HIV transmission to approximately 1 in 2 million blood component units transfused.[70] Multiplying the per-unit risk estimates by approximately 20 million components transfused to 5 million recipients per year in the United States leads to the expectation that fewer than 10 recipients per year are transfused with HIV-1-infected blood. The risk of HIV-2 transmission has been estimated at less than 1 in 15 million,[38] with other rare subtypes (e.g., HIV-1 subtype O)[22] being of even lesser concern. These combined risks are more than 10,000-fold lower than the risk existing at the peak of the transfusion-associated AIDS epidemic between 1982 and 1984.[57]

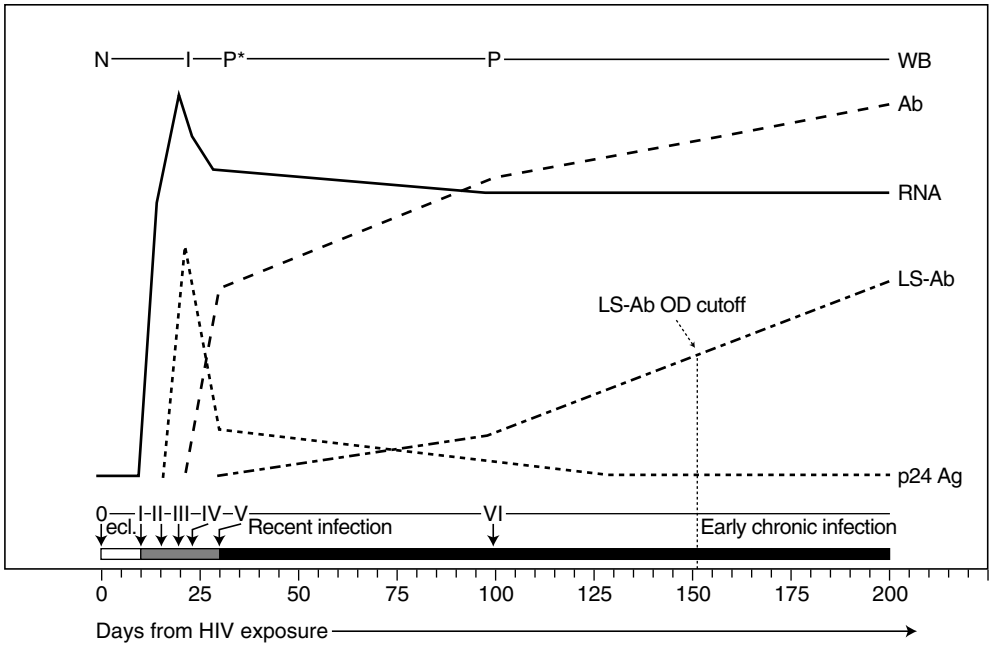

Figure 45–6 Schematic, semi-quantitative display of the progression of HIV markers (from top to bottom: WB, western blot; Ab, HIV antibody; RNA, HIV RNA; LS-Ab, HIV antibody determined by sensitive/less sensitive EIA testing strategy[90]; p24 Ag, HIV p24 antigen), from time of exposure (day 0) through the first 200 days of infection. As each of the markers appears in the bloodstream, the infection is assigned a new stage from 0, characterized by undetectable viral markers in blood samples, except for perhaps low-level viral blips[96]; through stage I (definitive HIV RNA viremia), stage II (p24 antigenemia), stage III (HIV EIA Ab reactive), stage IV (WB indeterminate, "I"), stage V (WB positive without p31 band, "P*"), and stage VI (WB positive, "P" with p31 band). Stages I–VI were derived from analysis of 435 serial samples from 51 plasma donors with new HIV-1 infection.[82] Incorporation of LS Ab EIA testing would allow further characterization of stage VI samples as representing recent vs. early chronic infection, i.e., infection that occurred within vs. beyond approximately 6 months from Ab seroconversion by an IgM-sensitive EIA.[90] The standardized optical density (OD) cutoff for the LS Ab EIA may be varied with recommended cutoffs from 0.5–1.0. Shown in the figure are the results for an OD cutoff of 0.75, as chosen in the original publication.[90] Cutoffs of 0.5 and 1.0 would result in average demarcations of recent from early chronic infection at 124 and 186 days, respectively. AIDS 2003;17:1871–1879.)

Investigators have frequently used calculations based on the incidence-window period model to project the risk of transmission of HIV and other viruses by transfusion in different geographic areas and at various periods of the epidemic. Experience over time has confirmed the validity of the approach, and the risk projections derived from the model are generally accepted as meaningful and reliable estimates of the true risk.[94,95] Decreasing projections of the magnitude of risk in the same population over time reflect removal of high-risk donors and improvements in blood donor screening. Recently, widespread use of NAT assays in blood donor screening led to application of a new strategy for estimating risk of HIV transmission based on rates of detection of recently infected donors.[72] The method takes into account the expected increase of viral genomic equivalents (viral load) in blood donor samples during the initial phase of viral replication before appearance of HIV antibodies.[72,82] By back-extrapolation of the viral load from a reference point such as appearance of p24 antigen or detection of HIV infection by minipool NAT to a minimal viral concentration that is thought to be infective (e.g., 1 viral copy per 20 mL plasma), the window period between the infectious threshold and the reference point can be projected. By substituting the reference point with a theoretical threshold such as assay sensitivity of a new NAT, the window period for that assay can be estimated. A practical application of the new method is the projection of risk reduction for transfusion transmission of HIV by testing individual donor samples rather than minipools of 16 to 24 samples. The result suggests a rather modest decrease in risk, from approximately 1 per 2 million component units transfused with MP-NAT, to 1 in 3 to 4 million units with ID-NAT,[82] at considerably higher cost and potentially delayed availability of transfusable cellular blood components. Not addressed by the novel strategy of estimating residual transmission risk of HIV based on viral replication dynamics is the finding of low-level (estimated 1 to 10 copies/mL) viral "blips" in the 2- to 3-week long period between infection and ramp-up phase of viremia, sometimes referred to as the *eclipse phase* of HIV infection (see Fig. 45–6). Such "blips" have been observed at intervals of approximately 1 to 3 weeks before HIV ramp-up viremia in 6 of 15 plasma donors with newly acquired HIV infection.[96] The added risk from blood donations during the eclipse phase is unknown, but might contribute slightly to the overall risk estimate associated with current NAT blood donor screening.[96]

HUMAN T-CELL LYMPHOTROPIC VIRUS

Although eclipsed by concerns about HIV, HTLV is nonetheless relevant to the safety of blood transfusion. Both HTLV-1 and HTLV-2 are transmitted by blood transfusion, cause chronic retroviral infection of humans, and are associated with serious disease outcomes. Serologic testing for HTLV-1 in U.S. blood donors has been in place since 1988. This policy has led to the unexpected discovery that at least half of blood donors testing positive for HTLV-1 are in fact

infected with HTLV-2, for which disease outcomes are less well described.[97–99]

Virology

Both HTLV-1 and HTLV-2 are human retroviruses of the oncornavirus class. As previously mentioned, the first report of HTLV-1 discovery was published in 1980 and that of HTLV-2 in 1982.[5,7] With RNA genomes of approximately 8000 nucleotides in length, the genetic organizations of HTLV-1 and HTLV-2 are similar to those of other retroviruses (Fig. 45–7).[100,101] The HTLV genome contains *gag* regions coding for viral core proteins, *pol* regions coding for viral reverse transcriptase, protease and integrase *env* regions coding for the viral envelope proteins, and finally the *tax* or *px* region (analogous to the HIV *tat* gene), which is responsible for transcriptional regulation of HTLV-1 and HTLV-2. HTLV-1 and HTLV-2 have approximately 60% nucleotide sequence homology. Many of their viral proteins crossreact serologically, although peptides eliciting specific immune responses and allowing differential serologic diagnosis of HTLV-1 versus HTLV-2 have been discovered.

HTLV-1 predominantly infects CD4+ T lymphocytes, whereas HTLV-2 has a broader tropism with preference for CD8+ lymphocytes and, to a lesser degree, CD4+ lymphocytes, B lymphocytes, and macrophages.[102,103] Neither virus has high levels of cell-free viremia, perhaps accounting for lower transmissibility than either hepatitis B virus or HIV. Also in contrast to HIV, there is relatively little active replication of HTLV-1 and HTLV-2 in infected humans. Instead, most expansion of the pool of infected lymphocytes appears to occur by lymphocytic division and the proliferation of clones of infected lymphocytes.[104] Corollaries of these observations are that descriptions of HTLV viral load refer to measurements of proviral DNA in the cellular compartment. There has been only one report of measurable HTLV RNA in cell-free plasma[105]; however, further research will be necessary to exclude the possibility of a significant viremia in cell-free plasma.

Epidemiology and Modes of Transmission

HTLV-1 is endemic in sub-Saharan Africa; the Caribbean region and parts of South America, including Colombia, Peru, and Brazil as a result of the slave trade; southwestern Japan; and parts of Melanesia and Australia.[106] HTLV-1 has also been reported from Iran, India, and Taiwan as well as in countries containing significant immigrant populations from the main endemic areas. Given the high HTLV-1 prevalence in southwestern Japan, the absence of HTLV-1 infection in mainland China and in Korea as well as other parts of Southeast Asia poses an epidemiologic puzzle. Molecular epidemiologic studies have indicated the presence of at least two viral subtypes in Africa; a cosmopolitan subtype found in Africa, Japan, the Caribbean, and other more recent foci of HTLV-1 infection; and a distantly related Melanesian subtype.[107]

HTLV-2 has also been found to be endemic in a number of Amerindian tribes throughout South, Central, and North America.[108–110] Not all tribes are infected, and tribes with the least intermingling with Western settlers, such as the Kayapo of Brazil, appear to have the highest prevalence rate.[108] The other endemic focus of HTLV-2 infection appears to be among Pygmies in sub-Saharan Africa, again in tribes having relatively little contact with European settlers.[111] HTLV-2 infection is also prevalent among injection drug users and their sexual partners in the United States, Brazil, and Europe.[112] Given the relative recency of injection drug use behavior, there appears to have been an epidemic spread of HTLV-2 over the past 40 or 50 years as a result of the introduction of endemic HTLV-2 into the injection drug use population and subsequent spread through sharing of contaminated needles.[113]

In endemic populations, both HTLV-1 and HTLV-2 show age-specific seroprevalence rates that rise steadily with age, from 1% or less among infected children to 5% to 10% of older individuals.[113–116] Female seroprevalence is generally greater than male seroprevalence, presumably owing to more efficient sexual transmission from males to females than vice versa.

In one large study of blood donors in the United States in the 1990s, HTLV-1 seroprevalence was approximately 10 per

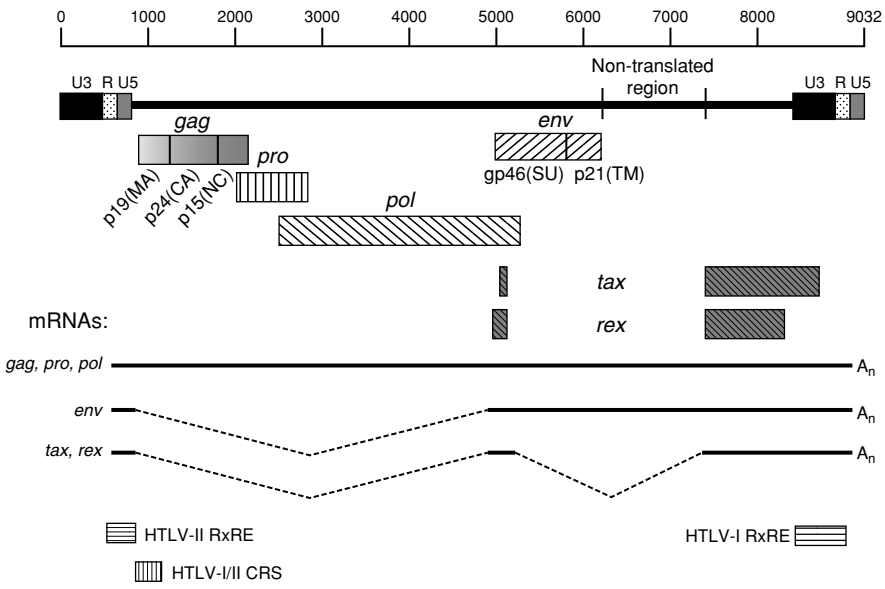

Figure 45–7 Structure and organization of the HTLV genome. The HTLV provirus genome is shown at the top of the figure. Positions of known genes are indicated. Sizes and positions of the proteins encoded by the provirus are shown beneath the provirus. The structure of the three messenger RNA species produced are shown at the bottom of the figure. (Reproduced with permission from Fields BN, Knipe DM, Howley PM (eds). Fields Virology, 3rd ed. Philadelphia, Lippincott-Raven, 1996, p 1850.)

100,000 overall, rising steadily with age, and was twice as prevalent in females as in males.[113] In contrast, HTLV-2 was found among the same U.S. blood donors at a rate of 20 per 100,000 overall.[113] Other studies of U.S. donors have shown similar overall prevalence, but a more equal ratio of HTLV-2 to HTLV-1.[114] Although there is at least a twofold female excess of infection, the age prevalence curve peaks in persons aged 30 to 49 and falls in older individuals (Fig. 45–8). This apparent birth cohort effect is consistent with the hypothesis of an epidemic of HTLV-2 transmitted by injection drug use and secondary sexual transmission beginning in the late 1960s and 1970s.[113]

HTLV-1 and HTLV-2 have similar modes of transmission. Mother-to-child transmission is important for both viruses, and between 20% and 30% of infants born to infected mothers become infected themselves.[117] In contrast to HIV, however, the great majority of such transmission appears to occur by means of breast-feeding. Public health intervention studies in Japan have documented a decrease in the transmission rate from 30% to 3% when infected mothers substituted bottle-feeding for breast-feeding.[117]

Sexual transmission also occurs for both HTLV-1 and HTLV-2, presumably by means of infected lymphocytes or other cells contained in seminal fluid.[118,119] The earlier impression that transmission from males to females is more efficient than vice versa and that HTLV-1 is more readily transmitted than HTLV-2 may not be true.[120] The most important factors determining whether transmission will occur between HTLV-serodiscordant couples (i.e., one seropositive and one seronegative for HTLV) are the total duration of the sexual relationship and the HTLV proviral load in the male.[121] The frequency or type of sexual activities performed appears to have little effect on the risk of transmission, although the predominant behavior in this study was heterosexual vaginal intercourse. The CDC recommends prevention of sexual transmission through the use of condoms by HTLV-serodiscordant couples as well as by HTLV-seropositive single individuals with multiple sexual partners.[121]

HTLV-1 and HTLV-2 are also transmitted efficiently by the sharing of contaminated needles or other parenteral exposures, leading to high seroprevalence among injection drug users.[112,122] Data on transmission by blood transfusion are provided in more detail later. There is no data supporting the casual transmission of HTLV-1 or HTLV-2 within households or between individuals who do not have any of the preceding risk factors for transmission.

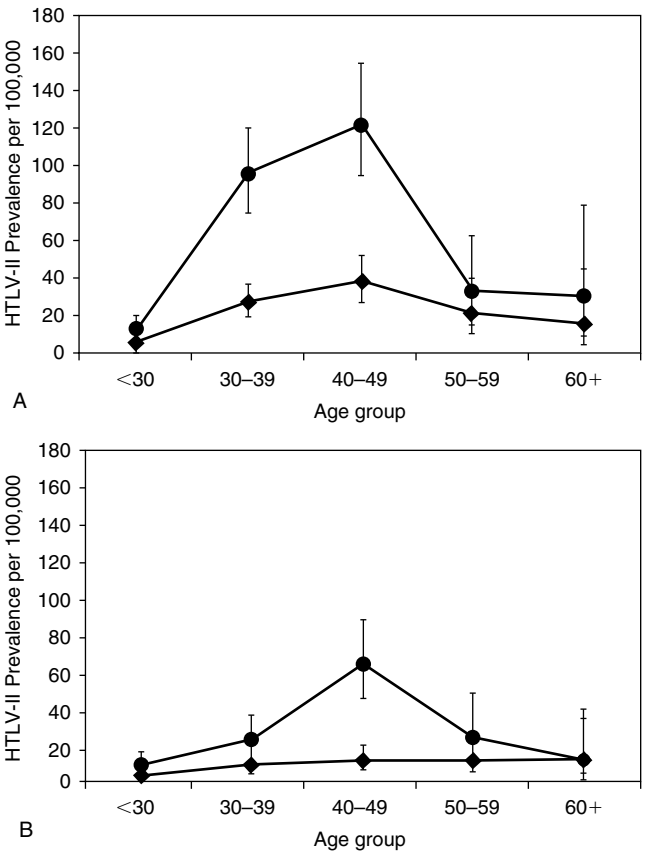

Figure 45–8 Age-specific seroprevalence of human T-cell lymphotropic virus type 2 among female **(A)** and male **(B)** blood donors in five U.S. cities participating in the multicenter Retrovirus Epidemiology Donor Study, stratified by two western *(solid circle)* and 3 eastern or central *(solid diamond)* blood centers. Seroprevalence is expressed per 100,000 donors.

Disease Outcomes

Soon after its discovery, HTLV-1 was associated with a CD4+ T-lymphocytic lymphoma, ATL.[123,124] This lymphoma, which has a leukemic phase in one fourth to one third of infected individuals, is also associated with hypercalcemia, skin lesions, and hepatosplenomegaly.[125] Atypical malignant lymphocytes with convoluted nuclei, referred to as *flower cells,* are seen in a high number of patients with leukemic-phase ATL and may also be seen in low numbers in asymptomatic persons who are seropositive for HTLV-1.[126,127] The prognostic implications of having flower cells are not well defined, although individuals with either very high HTLV proviral loads or with relatively high numbers of circulating flower cells appear to be predisposed to a higher risk of ATL.[128] An individual infected with HTLV-1 at birth has an estimated 4% lifetime risk of ATL, and the risk is presumably lower for those infected sexually as adults.[129] There are two case reports of ATL occurring after apparent transfusion-related HTLV-1 infection.[130] Chemotherapy is often less effective for ATL than for other lymphomas and leukemia, and a high mortality is associated with this hematologic malignancy.[131,132]

Although both HTLV-1 and HTLV-2 are known to cause spontaneous lymphocytic proliferation in vitro,[133–135] HTLV-2 does not appear to cause hematologic malignancy. Even though HTLV-2 was initially isolated from two cases of atypical T-lymphocytic hairy cell leukemia, subsequent epidemiologic studies of hairy cell leukemia have not revealed an association with HTLV-2 infection.[136–139] Similarly, initial case reports of mycosis fungoides and large granular cell leukemia among HTLV-2-infected persons have not led to confirmed associations after further investigation.[140–142]

The other major disease association of both HTLV-1 and HTLV-2 is HAM/TSP. Initially described by Gessain and colleagues[143] in Martinique, the association with HAM/TSP was soon confirmed by investigators in Japan and others.[144–147] HAM/TSP is a slowly progressive myelopathy characterized by spastic paraparesis of the lower extremity, hyperreflexia, bowel and bladder symptomatology, and relative sparing of both upper extremity strength and cognitive function.[148]

The disease course is slow but progressive, with 10 years often elapsing between the first signs and severe paraplegia necessitating the use of a wheelchair. There is no definitive treatment for HAM/TSP, although the use of systemic steroids, immunosuppression with azathioprine, and the use of the androgenic agent danazol have had transient success.[148] Clinical trials are planned to evaluate the efficiency of various treatment regimens.

A cohort study has estimated the risk of HAM/TSP to be about 2% in HTLV-1–positive persons.[149] Sexual acquisition of HTLV-1 may be a risk factor for HAM/TSP[150]; however, the incubation period may be shortest after transfusion-acquired infection.[151–153] Cases of typical HAM/TSP have been reported in HTLV-2–infected humans, although the risk appears to be slightly less than or equal to that with HTLV-1.[149] In contrast to some initial reports, there is no association of either HTLV-1 or HTLV-2 and classic multiple sclerosis.[154–156] Likewise, the implication of HTLV-1 and HTLV-2 in other neurologic syndromes is controversial, because individuals infected with HTLV-2 may have genetic or environmental factors that also cause neurologic disease.[157]

Other immunologic diseases and phenomena have been reported in relation to HTLV-1 and HTLV-2. HTLV-1 has been associated with lymphocytic pneumonitis and uveitis.[158,159] HTLV-1–positive cases of polymyositis have also been reported, and both HTLV-1 and HTLV-2 may be associated with a higher incidence of arthritis.[159–161] Of particular interest, a cohort study has shown that HTLV-1, and particularly HTLV-2, may be associated with a higher incidence of other infections, including pneumonia, acute bronchitis, and urinary tract infection.[162] This finding is consistent with the association of HTLV-1 and infective dermatitis in children.[163] The mechanism of these disease associations has not yet been described and may be due to either subclinical immune dysfunction or increased inflammation. It is not clear whether either HTLV-1 or HTLV-2 contributes to an increased incidence of other types of malignancy; a study in Japan has reported an increased risk of "viral-associated" malignancy such as hepatoma.[164] However, a study in the United States showed no increase of any nonhematologic malignancy with HTLV-1 or HTLV-2.[162] Intriguingly, infection with HTLV-2 but not HTLV-1 was found recently to be associated with increased mortality in blood donors.[165] In another recent study on the impact of co-infection with HTLV-1/2 in HIV-infected patients, co-infection with HTLV-2 was associated with a higher rate of clinical complications but paradoxically also with longer survival and delayed progression to AIDS.[166] However, a well-designed meta-analysis, which accounted for date of HIV infection, showed no effect of HTLV-2 co-infection on HIV disease progression.[167]

Transfusion-Related Transmission

Soon after its discovery, HTLV-1 was shown to be transmitted by blood transfusion, with transmission efficiency in Japan of at least 50%.[168,169] A cohort study in Jamaica in the late 1980s demonstrated a 25% to 30% risk of HTLV-1 infection after transfusion of one unit of HTLV-1-infected blood, with a 50-day mean latency period between the implicated transfusion and the development of de novo anti-HTLV antibodies.[170] Results of the TSS in the United States, with data from the mid-1980s, showed a much lower rate of transmission, only 10% to 20% for HTLV-1 and HTLV-2.[171] Differences between these transmission rates may be due to the requirement that HTLV-infected, viable lymphocytes must be present in the transfused unit for it to be classified as infected. A significant inverse correlation between the duration of refrigerated storage (presumably related to lymphocyte viability) and the risk of HTLV transmission was demonstrated in the TSS. Although such data were not reported, it is conceivable that blood unit storage times were shorter in the Japanese and Jamaican studies than in the U.S. study, and therefore viable infected lymphocytes were more frequently transfused.

A later study of recipients of large-volume transfusions in the United States showed estimated risks of HTLV transmission to be 12 per 100,000 units before and 1.4 per 100,000 units after the 1988 institution of universal screening for HTLV antibodies.[88] The screening was introduced in that year after consideration of early data on HTLV-1 prevalence in blood donors, its transfusion transmissibility, and diseases associated with the infection.[114] Studies estimating the current risk of HTLV-1 by blood transfusion, similar to those of other low-frequency agents, are hindered by the large sample sizes required to measure low-frequency events. Nonetheless, the Retrovirus Epidemiology Study and the American Red Cross (ARC) have measured the incidence of HTLV-1 and HTLV-2 infection among serial blood donors and have used these data, along with estimates of the window period between infection and the development of antibodies, to model the residual risk of HTLV-1 infection. The most recent published projections, based on voluntary donations to the ARC system from 2000 to 2001, estimated a residual risk of approximately 1 per 3 million transfused units for HTLV-1, which is lower than the current risk of HIV and hepatitis B or C infection, and evidence of further dramatic risk reduction since the early 1990s.

The risk of transmission of HTLV-1 by cell-free plasma is controversial. The Jamaican study showed no episodes of transfusion transmission in individuals receiving only plasma transfusions,[170] and laboratory studies have shown that cell-free transmission of HTLV-1 is difficult. A report on the detection by RT-PCR of HTLV-1 viral RNA in cell-free plasma is of concern, if its findings can be replicated.[105] Nonetheless, transfusion of blood products containing residual leukocytes appears to carry a higher risk of HTLV transmission than transfusion of products free of leukocytes.[90]

Also of note in regard to transfusion safety is the definite association between HTLV-2 infection and previous injection drug use or sexual relations with an injection drug user. Because injection drug users are more effectively screened out of the blood donor population, the typical HTLV-2-infected individual is a middle-aged woman who reports remote sexual exposure to an injection drug user. These data highlight the need to continue refining behavioral screening criteria, including consideration of banning donors who admit any prior sexual contact with injection drug users.[172]

Laboratory Diagnosis

Screening for HTLV-1 and HTLV-2, analogous to HIV screening, is generally performed with EIAs. The earliest assays included only HTLV-1 native viral proteins. It soon became apparent, however, that these assays were deficient in the native HTLV envelope proteins because of the viral purification process used to produce the proteins. This problem led to the subsequent addition of recombinant envelope proteins to the EIA antigen mix to improve the test's sensitivity. Because HTLV-1 and HTLV-2 have 60% nucleotide sequence

homology, there is significant cross-reaction of HTLV-2 with HTLV-1 EIAs.[101] However, because 10% to 15% of HTLV-2 infections were missed by earlier HTLV-1 EIAs,[173] subsequent EIAs utilized a recombinant transmembrane envelope glycoprotein, rgp21, that had greater sensitivity for both HTLV-2 and HTLV-1, and later generations of EIAs use recombinant proteins from both HTLV-2 and HTLV-1. Thus, the FDA has permitted the labeling of single assays for the combined detection of HTLV-1 and HTLV-2.

Supplemental testing for HTLV-1 and HTLV-2 has continued to be more problematic. The earliest and most common supplemental test is the Western blot. Because of a deficiency in viral envelope protein, however, Western blots using only HTLV-1 native viral proteins are relatively nonspecific and may also be insensitive to HTLV-2. Western blots supplemented with rgp21, which have greater sensitivity to HTLV-2 because of its crossreactivity with rgp21, soon became available. However, false-positive reactivity to rgp21 in combination with nonspecific reactivity with the *gag* p19 or p24 bands occasionally led to false-positive Western blot interpretations.[174] Radioimmunoprecipitation has been used in research laboratories over the years to more specifically confirm the presence of antibodies to envelope proteins of HTLV-1 and HTLV-2. However, this assay is very labor intensive and so is not suitable for use as a routine supplemental test in blood banks.

Second-generation Western blots have been developed that contain native HTLV-1 proteins supplemented with a refined version of rgp21, to decrease nonspecific reactions, in addition to recombinant peptides specific to both HTLV-1 (rgp46-I) and HTLV-2 (rgp46-II).[175,176] In the research setting, these assays have proved to be both sensitive and specific for the diagnosis of HTLV-1 and HTLV-2. Because of the presence of the type-specific epitopes, they allow the differentiation of HTLV-1 from HTLV-2 infection in the great majority of cases.[177,178] HTLV type-specific peptides are also available in the EIA format; however, these tests should be used for typing specimens that have already been confirmed by other supplemental assays.[177–179] This issue is important, because counseling of the infected donor should be specific to the disease outcomes to be expected with either HTLV-1 or HTLV-2, and risk factor profiles have been shown to be specific to either HTLV-1 or HTLV-2.[122]

Few of the HTLV supplemental tests described have been licensed by the FDA, however, so they have been used only under provisions for research. Thus, the counseling of infected donors based on the results of such tests has carried potential regulatory risks. In addition, because of the complexity of some of these supplemental assays, proficiency of the laboratories performing them depended on the local expertise and the volume of supplemental testing performed. This situation has led the FDA to ban the use of nonlicensed supplemental assays in the diagnosis of blood donors who test positive on the HTLV EIA. Although the regulatory reasons for this decision are understandable, it has significantly reduced the specificity of the diagnosis of HTLV-infected blood donors, because only 10% to 25% of EIA-positive blood donors are in fact seropositive for HTLV-1 or HTLV-2, and donors with indeterminate EIA results are unlikely to be infected with HTLV in the absence of definite risk factors.[180] The lack of accurate licensed supplemental tests means that a large number of HTLV EIA-positive donors are falsely being informed that they are potentially seropositive for HTLV. Thus, there is an urgent need for the development of licensed supplemental assays that would differentiate HTLV-1 and HTLV-2 infections.

Less clear is the need for improving the sensitivity of HTLV blood donor screening by implementing NAT-based HTLV testing. Lower incidence rates of infection than seen for the other major transfusion-transmitted viruses, at least partial protection of blood recipients from HTLV transmission by widespread use of leukoreduced cellular blood components, and low disease penetrance in the 5% range argue against such a proposition, especially if cost effectiveness is considered. On the other hand, tolerance of even a low risk of retroviral infection has not been acceptable in a political environment that demands zero risk. Before large-scale blood donor screening with HTLV NAT assays could be introduced, however, technical issues would also have to addressed. Current NAT systems do not have the capacity to extract cell-associated nucleic acids, so detection of HTLVs (and other cell-associated pathogens, including parasites) by NAT will have to await a new generation of high-throughput screening systems.

ADDITIONAL RETROVIRUSES

Besides HIVs and HTLVs, there may be additional human retroviruses that have not as yet been discovered. It is also now well established that retroviruses from other species can be transmitted to humans and subsequently pose a risk to the blood supply. These concerns led some to call for active surveillance for new and emerging retroviruses with potential relevance for transfusion safety. Indeed two new HTLV variants, tentatively named HTLV-3 and HTLV-4, have been isolated from a few human Pygmies and Bantu living in remote areas of sub-Saharan Africa.[181,182] Because the infected humans hunted and butchered monkeys or kept them as pets, the authors suggest that recent cross-species transmission may have occurred.

Interestingly, it is known that 5% to 10% of the genomes of humans and many other species is comprised of endogenous retroviral sequences. The origin and functions of human endogenous retroviral (HERV) sequences remain unclear, although it is generally believed that these sequences represent relics of ancestral retroviral infections that have been conserved through evolution for functional properties, including protection from exogenous retroviral infection. To date there is no convincing evidence that HERVs are associated with any disease or that they can be transmitted horizontally by blood transfusion or other routes. However, there is concern that endogenous retroviruses in the genomes of other species could be activated into exogenous retroviruses and be transmitted to humans.[183,184] This was highlighted recently by demonstration of in vitro transmission of porcine endogenous retrovirus sequences to human cells.[183] The potential of cross-species infection is of particular concern with animal-derived blood constituents (e.g., porcine-derived clotting factors, bovine albumin, equine immunoglobulins) or organs in xenotransplantation protocols. Reassuringly, recent studies to examine the issue of whether endogenous retroviruses from other species may have infected humans exposed to blood products or organs from these species have failed to document any cases of infection using sensitive serologic and molecular assays.[184,185]

A further concern that has been raised regarding cross-species transmission of exogenous retroviruses is the potential that such transmissions could result in accelerated

transmission patterns and increased pathogenicity with humans, similar to what likely happened with SIV/HIV. For example, a clinical syndrome called idiopathic (HIV-negative) CD-4 lymphocytopenia, described in the early 1990s, was speculated to result from a novel retrovirus infection. However, subsequent studies both in high-risk and blood donor populations failed to confirm a retroviral or other infectious etiology, with the exception of a subset of cases due to group O HIV-1.[186] There has also been speculation over the years that donors with indeterminate seroreactivity for HIV or HTLV may harbor crossreactive primate or ungulate retroviruses.[187] However, most studies that have probed samples from donors with indeterminate test results have failed to identify evidence for infection based on type-specific serologic or PCR analyses.[187]

Over the past several years novel assays have been developed that allow for investigation of donor and other specimens for evidence of unknown retroviruses. These include amplified reverse transcriptase assays (Amp-RT), also called *product-enhanced RT assays* (PERT), and generic PCR assays that target conserved regions of polymerase and *gag* genes that are common among highly divergent retroviral families. Continued application of these tools to samples from blood donor–recipient repositories, both in developed and developing countries, will be important to reassure the public that additional retroviral agents do not pose a risk to blood safety.

APPROACHES FOR FURTHER REDUCING THE RISK OF RETROVIRAL TRANSMISSION BY TRANSFUSIONS

Twenty years of blood donor screening for HIV and HTLV, including utilization of sensitive NAT technology for HIV RNA detection since the late 1990s, have greatly contributed to improved blood safety with regard to retroviral transmission in high-income nations that can afford and support the required infrastructure for sophisticated blood screening programs. Yet, despite the now exceedingly small likelihood of becoming infected with HIV or HTLV from a screened blood transfusion, there continues to be the call for and expectation of a blood supply that is risk free in regard to HIV and other infectious disease transmission.

Principal avenues that are actively being pursued in the effort to eliminate transfusion-transmitted retroviral infections are the selection of the safest possible donor populations, continuing improvements in blood donor testing, and introduction of safe, effective, and affordable viral inactivation methods into transfusion practice.

Because of the disproportionate impact of the HIV epidemic on poor urban racial minorities and the known higher prevalence of HIV among minority donors, some have argued for what has been termed *demographic recruitment*. However, this concept fails to recognize the critical need for a genetically diverse donor base to support the transfusion needs of a similarly diverse recipient population. Others have proposed expanding or modifying the risk factor interview process by, for example, adding questions on recent heterosexual activity, using cartoon depictions of risk behaviors to improve understanding by less-educated donors, and implementing computer-based interview strategies to enhance confidentiality.[188] Convincing data to support these proposals have not been generated, however.[189] Risk factor profiles of seropositive donors have changed over time. For example, Petersen and associates[190] compared HIV risk factors among 508 seropositive donors identified at 20 blood centers between May 1988 and August 1989 with those of 472 seropositive donors identified from January 1990 through May 1991. The overall rate of seropositive donations declined slightly over time (from 0.021% to 0.018%), primarily as a result of a decrease in infected donations by homosexual and bisexual men. In contrast, the rate of infected donations by persons probably exposed through heterosexual contact remained stable. Toward the end of the observation period, 56% of infected female donors and 12% of infected male donors had seropositive heterosexual partners; another 41% of infected female donors and 29% of infected heterosexual male donors were probably infected by heterosexual contact (on the basis of serologic studies for sexually transmitted disease markers), even though specific infected sex partners could not be identified. These researchers rejected the option of deferring donors on the basis of recent or lifetime number of heterosexual partners, because numeric cutoffs that would identify only half of the seropositive heterosexual donors would also result in a loss of 7% to 13% of all donations. This study illustrates the significant tradeoffs required to maintain an adequate as well as safe blood supply.

Incentives for blood donors pose a similar dilemma. Paid blood donors have long been identified as having a higher risk for transmissible viral diseases, and a volunteer-only blood donor system is considered a cornerstone in ensuring blood safety.[191] Nonmonetary incentives are widely used to attract volunteer donors, however, and surveys have shown that some of these incentives may also entice high-risk donors to give blood.[192]

Since implementation of NAT testing in the so-called *mini-pool format*, strategies to further improve blood donor screening for HIV focus on introduction of individual donation (ID) testing. As studies have shown, however, the expected additional risk reduction from ID-NAT testing would be modest,[72] and complete elimination of transmission risk is unlikely to be achieved by blood screening alone.

An added layer of safety is provided by viral inactivation technology, which has been used for almost 2 decades in the manufacturing of plasma derivatives and almost as long for treatment of pooled plasma in many European countries.[193] Various methods are being used, with solvent-detergent treatment being the most common principle employed.[194] Effectiveness of the solvent-detergent method is very high for lipid-enveloped viruses, including HIV and HTLV, but the procedure does not reliably inactivate nonenveloped viruses.[195] The safety of the solvent-detergent treatment process for fresh frozen plasma came under further scrutiny by the finding of preferential inactivation of antithrombotic proteins in treated plasma that could result in a prothrombotic state in large-volume recipients. Reports of venous thrombotic events (VTE) in patients receiving exchange transfusions with solvent-detergent–treated fresh frozen plasma,[196,197] and several fatalities associated with VTEs in liver transplant patients who received solvent-detergent–treated fresh frozen plasma, contributed to the discontinuation of use of the product in the United States, although it is still available in Europe.[195]

Newer chemical, photodynamic, and photochemical methods capable of inactivating a wide range of pathogens, including known transfusion-transmissible viruses, bacteria, and parasites, have been developed. These work with single-donation platelets and fresh frozen plasma components, thereby

avoiding the risks associated with pooling of blood components.[193] One photochemical inactivation system was licensed in Europe in early 2002; however, licensing in the United States has been delayed for now. Systems of pathogen inactivation of red cell products are at an earlier stage of development and clinical study and are therefore further away from possible implementation.[195] An impediment to the introduction of any new viral inactivation method for blood components is the concern that these methods may themselves pose adverse consequences for transfusion recipients, potentially offsetting the benefits of the new treatment method in comparison with existing strategies. Pathogen inactivation methods are discussed in more detail in Chapter 27 .

An ongoing struggle is the prevention of transfusion-transmitted retroviral and other infections in low-income and developing nations. Burgeoning prevalence and incidence rates as well as lack of resources make effective blood donor screening in these areas a challenge that has only been partially met. It is hoped that blood safety in developing countries can be improved gradually through establishment of sufficiently funded national and regional programs that incorporate establishment of donor recruitment networks and high-quality screening capacity.[198]

Chapter 46

Human Herpesvirus Infections

John D. Roback

INTRODUCTION

The Herpesviridae is a family of approximately 100 viruses with common structural features. Each virus has a linear 120- to 230-kb double-stranded DNA genome maintained in a toroidal conformation and surrounded by an icosadeltahedral nucleocapsid. The 100 nm diameter capsid, composed of 162 capsomeres, is encompassed by a dense tegument or matrix and an outer trilaminar lipid envelope that contains proteins of both viral and host cell origins.[1] Herpesviruses share a number of biologic characteristics as well, including expression of viral enzymes that participate in DNA synthesis and nucleic acid metabolism, confinement of viral DNA synthesis and packaging to the host cell nucleus, destruction of the infected cell during active viral replication, and capacity to remain in a latent state indefinitely.[1]

Of the herpesviruses, eight are known to infect humans (Table 46–1). Members of the human herpesvirus (HHV) family are categorized into three subfamilies based on biologic properties including cell tropism, genome structure, and sequences of conserved open reading frames (ORFs). Most have a commonly employed name, such as cytomegalovirus (CMV); each is also known by an accompanying HHV designation, according to guidelines from the International Committee on Taxonomy of Viruses (e.g., CMV is HHV-5).[2] This chapter focuses primarily on CMV, the herpesvirus with most clinical relevance to transfusion medicine, along with discussion of other leukocytotropic herpesviruses (Epstein-Barr virus [EBV], HHV-6, HHV-7, and HHV-8) that may contaminate blood components.

CYTOMEGALOVIRUS (HHV-5)

Molecular and Cellular Virology of CMV

Viral Structure

CMV was the first identified betaherpesvirus and remains the prototype of this group. The CMV virion contains a linear double-stranded DNA genome of approximately 230 kbp in length, the largest of the herpesviruses.[3,4] The genome is divided into unique long (UL) and unique short (US) segments, each flanked by a pair of inverted repeat regions.[4] The UL and US segments can each independently invert with respect to one another, yielding four different genomic isomers. After infection, the termini of the linear genome are joined to produce a circular, or concatemeric, replicative form.[5] Circularized CMV genomes have also been identified in latently infected peripheral blood CD14+ leukocytes.[6] At least 200 ORFs have been identified within the CMV genome, many of which encode viral proteins of still unknown function.[4] After translation, viral proteins may undergo modifications, including phosphorylation, glycosylation, and cleavage. Mature virions range from 150 to 200 nm in diameter[7] and contain approximately 30 viral proteins distributed in the capsid, tegument, and envelope. Recently, viral RNA transcripts have also been identified packaged with viral DNA in mature virions.[8] This appears to be a relatively nonspecific process, mediated by viral proteins, including the tegument protein pp28, because cellular RNA transcripts are also incorporated into the virions.[9,10] The function of these packaged RNA transcripts is unclear, but they may allow viral protein translation to begin immediately on infection.[8] Additionally, in analogy with structural studies of retroviruses,[11] packaged RNA transcripts may also be important to the integrity of the viral particles.

Biology of Infection

VIRAL–CELLULAR INTERACTIONS

CMV can infect a range of cell types, including those of endothelial, epithelial, mesenchymal, hematopoietic, and neuronal lineages, frequently causing characteristic cellular enlargement (cytomegalia).[4,12] Infection appears to involve three sequential steps: viral attachment to the target cell, fusion of the viral and cellular membranes, and penetration of the viral capsid into the cell. Each step may require interactions between multiple viral coat proteins and cellular membrane proteins, the latter serving the role of viral receptors. The observation that the CMV genome contains at least 54 ORFs that encode putative viral membrane glycoproteins[13] hints at the potential complexity of these processes.

Viral attachment, the formation of a low-affinity dissociable viral–cellular interaction, involves interactions between viral proteins and cell surface receptors. One receptor class consists of ubiquitously expressed cell surface heparan sulfate proteoglycans, which appear to interact with the viral glycoprotein M/N (gM/gN) and/or gB envelope complexes and are required but not sufficient for infection.[14–18] The viral gB complex (sometimes called gcI, UL55, or gp130/55) is a disulfide-linked complex composed of 120- to 130-kDa and 55- to 60-kDa viral glycoproteins. The most abundant component in the viral envelope, gB is also a prominent target of neutralizing antibodies produced during natural infection.[15] gB binds to multiple cellular receptors. The epidermal growth factor receptor (EGFR) appears to be one member of this group of receptors.[19] Viral gB stably docks with EGFR and can displace EGF from its binding site. CMV infection leads to EGFR phosphorylation, Akt activation, and calcium mobilization. Furthermore, cell lines that did not express

Table 46–1 **Human Herpesviruses**

Subfamily	HHV Designation	Common Name
Alphaherpesvirinae	HHV-1	Herpes simplex-I (HSV-1)
	HHV-2	Herpes simplex-2 (HSV-2)
	HHV-3	Varicella-zoster virus (VZV)
Betaherpesvirinae	HHV-5	Cytomegalovirus (CMV)
	HHV-6A, -6B	—
	HHV-7	—
Gammaherpesvirinae	HHV-4	Epstein-Barr virus (EBV)
	HHV-8	Kaposi's sarcoma-associated herpesvirus (KSHV)

EGFR were resistant to CMV infection.[19] Because hematopoietic target cells do not express EGFR, other unidentified docking receptors for gB are probably involved. gB also activates Toll-like receptors, conserved cellular membrane proteins involved in initiating antipathogen responses.[20]

Although attachment complexes are initially dissociable, they can be stabilized by membrane fusion. After attachment, interactions between gB and its receptors may initiate fusion. In addition, the viral protein complex gp86 (gcIII, UL75:UL115, or gH:gL) appears to be involved in these processes.[21] Evidence indicates that gp86 is composed of the viral gH and gL proteins, as well as a third component not yet identified.[22] The cell membrane receptor for gp86 has been identified as a 92.5-kD constitutively phosphorylated glycoprotein.[23,24] Binding of gB and gp86 to the target cell initiates signaling processes that may be important to CMV infection. Interactions between gB and its cellular receptor(s) activates signal transduction through the interferon-response pathway, leading to induction of the interferon-responsive genes *OAS* and *ISG54*,[25] and binding of gp86 to the cellular 92.5-kD protein can alter intracellular calcium concentration.[26]

After fusion, the viral capsid penetrates into the host cell and releases viral DNA. The molecules mediating these processes have not been identified. Additional proteins have also been hypothesized to mediate viral infection. For example, cellular human leukocyte antigen (HLA) class I proteins may promote viral attachment through interactions with β_2-microglobulin attached to the virion membrane.[27]

VIRAL LIFE CYCLE

Active and Latent Infections After the steps of viral attachment, fusion, and penetration, active infection occurs if the target cell is permissive for the complete sequence of viral gene expression, viral genome replication, and production of progeny virions. During active infection, viral genes are expressed in coordinated waves. Three distinct kinetic classes of viral genes have been identified: immediate early (α), followed by delayed early (β) and then late (γ).[4] α-Class gene transcription is controlled by a combination of constitutively expressed host cell proteins and viral proteins present in the infecting virion. Thus, α genes can be transcribed in the presence of pharmacologic inhibitors of protein synthesis. Viral α proteins, in turn, are required for expression of viral genes of the β and γ classes.[28–30] The β protein products perform viral DNA replication and metabolic functions; the γ genes encode structural proteins required for assembly of progeny virions. Finally, mature virions are transported through the Golgi apparatus and are released from infected cells by exocytosis,[31] eventually resulting in host cell destruction.

Cytomegalovirus may also assume a latent state when it infects target cells that are not permissive for viral replication. Latency, the presence of viral DNA in an infected cell in the absence of active viral replication, may persist indefinitely because the host cell is not destroyed by the virus. The latent CMV genome retains the capacity to reactivate viral gene expression, produce infectious virions, and enter lytic growth at a later time. Studies with human and murine CMV have demonstrated that latency can be established in hematopoietic cells, primarily those of the granulocyte-monocyte lineage, as well as in endothelial cells.[32–38] The possibility of CMV latency in other cell types has not been excluded. The molecular mechanisms regulating CMV latency and reactivation from latency have not been completely elucidated. In the herpesvirus EBV, a clearly defined set of viral proteins have been identified that control latency and reactivation.[39] Similarly, CMV latency-associated transcripts (LATs) have been detected in 0.01% to 0.001% of sorted CD33+ lineage-committed hematopoietic progenitors from the peripheral blood of naturally infected individuals.[36,40] CMV LATs are transcribed from the viral IE gene locus and encode immunogenic viral proteins that are targets of naturally arising antibodies in CMV-seropositive individuals.[32,40,41] The function of LATs is currently unknown. Circularization of the CMV genome is associated with latency in CD14+ peripheral blood monocytes in CMV-seropositive individuals,[6] a phenomenon also seen during latent infections with other herpesviruses.[42–44] The possibility of persistent viral infections, an intermediate state between active and latent infection in which low levels of virus are produced, remains a topic of considerable debate.[45,46]

Viral Genes Important to Pathogenesis In addition to viral proteins that control expression of viral genes and virion assembly and provide structural support for the viral particle, CMV also encodes proteins that favor viral replication at the expense of host cell metabolism and disrupt the host's ability to combat viral infection. For example, CMV infection alters the expression, accumulation, and activity of the cellular tumor suppressor proteins, cyclins, and cyclin-associated kinases. These alterations in the cellcycle machinery act to simultaneously promote progression toward the G_1/S transition but prevent cellular DNA synthesis and cell division, resulting in cell-cycle arrest and cellular aneuploidy. It has been hypothesized that in the arrested state cellular DNA synthesis would be blocked but the cellular milieu would contain abundant nucleotides and other metabolic precursors that could support viral replication.[47–50] One viral protein involved in this process is the immediate-early IE1

72-kDa protein, which complexes with the cellular Rb-related protein p107 and blocks its ability to repress E2F-responsive promoters.[51] The IE1-mediated derepression at the level of E2F, in turn, allows expression of cellular genes that promote cell-cycle progression.[51] CMV infection also activates cyclin-dependent kinase 2 (CDK2), a cellular protein that controls progression through the G_1 and S phases of the cell cycle. The importance of CDK2 to viral replication was illustrated by blocking CDK2 activity with either a dominant-negative mutant or the pharmacologic inhibitor roscovitine. In both cases, inhibition of CDK2 activity prevented CMV replication and production of progeny virus.[50]

Cytomegalovirus has also developed mechanisms to interfere with antiviral immune function (reviewed in Hengel and colleagues[52] and Reddehase[53]). The UL37 ORF of CMV encodes vMIA, an anti-apoptotic protein that localizes to the mitochondria and protects infected cells from immune-mediated apoptosis by blocking the effects of Fas, tumor necrosis factor receptor-1 (TNFR-1), and granzyme B.[54] Monocytes are a prominent site of CMV latency, and monocyte-derived macrophages can support active CMV replication. During differentiation to macrophages, CMV in monocytes displays delayed replication kinetics and viral particles are retained in the Golgi apparatus, which may facilitate immune evasion until sufficient progeny virions have been produced.[55] In contrast, in patients with compromised antiviral immunity, CMV can replicate with rapid kinetics, displaying viral doubling times approaching 24 hours.[56]

Despite sophisticated viral mechanisms of immune evasion, clinical and experimental evidence demonstrates that the competent immune system can effectively suppress viral replication. For example, the murine CMV gp40 and gp48 glycoproteins (ORFs *m152* and *m06*, respectively) can decrease expression of cellular class I major histocompatibility complex (MHC) proteins during infection of fibroblasts and thus decrease CMV antigen presentation to CD8+ T cells. However, the significance of these mechanisms during natural infection are unclear because CMV infection does not disrupt class I MHC expression and antigen presentation in macrophages, the professional antigen-presenting cell most important in initiating the anti-CMV immune response.[57] Furthermore, although human CMV has also evolved mechanisms to interfere with antigen presentation by infected cells,[58,59] the immune system circumvents these obstacles by utilizing structural proteins in the infecting viral particle as immunodominant epitopes for an immune response.[60,61] Thus, the immune response can be initiated before expression of antiviral proteins that halt antigen presentation by the infected cell. CMV has also developed strategies to interfere with interferon-γ (IFN- γ) signals that normally upregulate MHC expression during viral infection.[62] Interestingly, downregulation of class I MHC cell surface expression by CMV should lead to destruction of the infected cells by host natural killer (NK) cells.[63] However, expression of the viral class I MHC homologue m144 by murine CMV decreases the susceptibility of the infected cell to NK-mediated lysis.[64]

CMV Infection, Immune Response, and Diagnosis

Transmission, Prevalence, and Epidemiology

During CMV infection, active viral replication results in shedding of infectious virions into plasma and bodily fluids, including saliva, tears, breast milk, urine, stool, and semen. Community-acquired CMV infection is usually the result of close contact with a person shedding CMV. The incidence of community-acquired CMV infection varies with the study population. For example, the yearly CMV seroconversion rate in health care workers has been estimated at 0.6% to 3.3%,[65] similar to rates of 2.0% to 6.3% reported in middle-class women during and between pregnancies.[66] In contrast, rates as high as 13% per year have been observed in adolescents.[67] In blood donors, the CMV seroconversion rate is estimated at approximately 1% per year.[68] Most studies have shown that 50% to 80% of the population is CMV seropositive,[4] although the incidence can be higher in some urban populations and lower in some groups of blood donors.[69]

Most individuals contracting community-acquired CMV infection are immunocompetent, and the infection is often asymptomatic. However, a mild self-limited infectious mononucleosis syndrome can occur, with symptoms that include fever, malaise, hepatosplenomegaly, and a rash.[70] CMV can be isolated from bodily secretions during the symptomatic phase. The infected individual mounts both a humoral and cell-mediated immune response and viral symptoms rapidly resolve, leading to a complete recovery. However, despite effective control of CMV infection by the competent host immune system, the virus is not completely eliminated but instead becomes latent.

Transplacental transmission of CMV to a developing fetus is an important viral cause of birth defects.[71,72] Fetal infection occurs in 40% to 50% of cases in which a seronegative mother contracts a primary CMV infection during pregnancy.[73,74] CMV disease occurs in 5% to 15% of the infected infants, presenting most often with intrauterine growth retardation, deafness, mental retardation, blindness, and thrombocytopenic bleeding.[72,73] However, when mothers are seropositive before pregnancy, maternal antiviral immunity can limit congenital CMV infection and disease. For example, in one study of seropositive mothers the rate of vertical transmission was approximately 1%.[73] Furthermore, no cases of symptomatic CMV infections were seen in 27 congenitally infected infants born to seropositive mothers.[73]

Cytomegalovirus can also be transmitted by blood transfusion or transplantation of hematopoietic stem cells and solid organs from infected donors. When the recipients are immunocompromised, CMV transmission through these mechanisms can produce serious clinical consequences. Prevention of CMV infection is an important concern in transfusion medicine.

CMV Infection of Peripheral Blood and Marrow Cells

CELL TROPISM

From the perspective of transfusion medicine, the most important target cells of CMV infection are peripheral blood leukocytes and their progenitors. Under appropriate conditions, these cell types can either harbor latent CMV or allow active viral replication, and thus are well-suited to mediate transfusion-transmitted CMV infection.

CMV infection of bone marrow hematopoietic progenitor cells likely occurs during primary infection[75] (Fig. 46–1). Most evidence suggests that these cells restrict viral replication but support viral latency,[32,33] although some studies have shown low levels of CMV replication in bone marrow–derived cells in culture.[75,76] CMV DNA has been identified

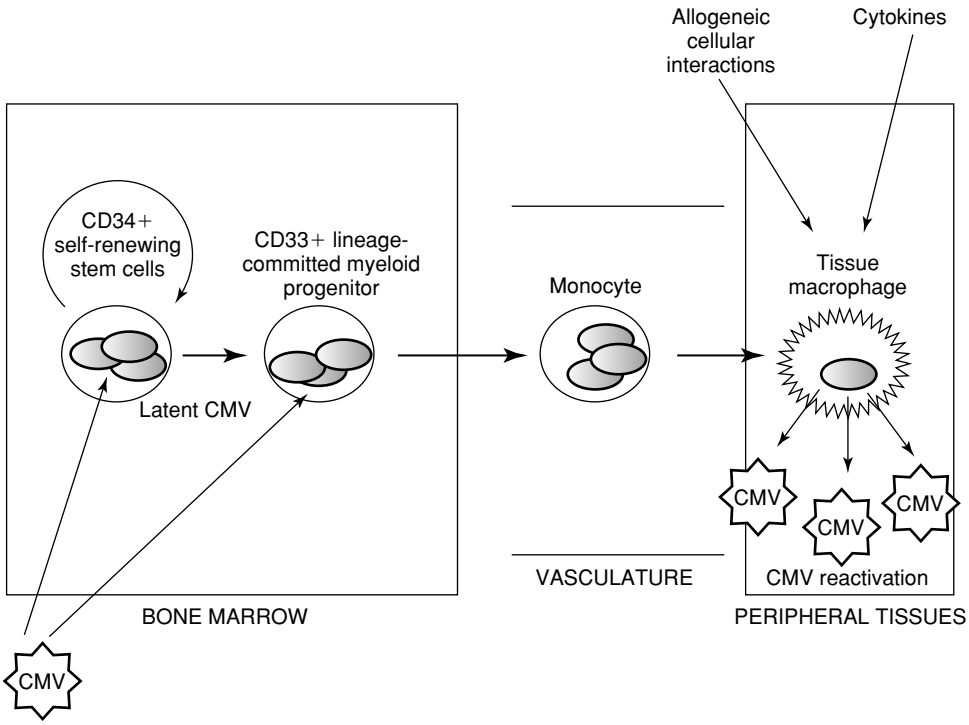

Figure 46–1 Hypothetical model integrating long-term latency of cytomegalovirus (CMV) in the hematopoietic compartment with transmission of CMV by blood transfusion and hematopoietic stem cell transplantation. CMV infects CD34+ multipotent progenitors during primary infection, and latently infected cells retain the viral genome during self-renewal. Committed progenitors in the marrow may also be directly infected with CMV. Either cell type may transmit CMV to a seronegative transplant recipient. CMV remains latent as CD33+ progenitors differentiate into circulating peripheral blood monocytes. Latently infected monocytes subsequently differentiate into tissue macrophages, either in the original host or after transfusion into a recipient. The allogeneic or cytokine-mediated signals monocytes encounter during differentiation render them permissive to CMV reactivation and viral replication. See text for detailed discussion.

by polymerase chain reaction (PCR) in sorted multipotent CD34+ progenitor cells from the bone marrow of seropositive, and in some cases seronegative, donors.[33,36,77,78] Because of their capacity for self-renewal, latently infected hematopoietic progenitor cells represent a potential long-term reservoir of latent virus. In fact, when CMV-infected CD34+ cells are grown in suspension cultures, transfer of CMV DNA to progeny cells during mitosis has been demonstrated.[34] CMV DNA has also been identified in myeloid-lineage-committed CD33+ progenitor cells in the marrow or mobilized into the peripheral blood by granulocyte-macrophage colony-stimulating factor. Lineage-committed progenitors appear to be latently infected, as indicated by the presence of CMV LATs in 0.01% to 0.001% of sorted CD33+CD14+ or CD33+CD15+ bone marrow cells from seropositive donors.[36] These findings support a model for latency in which early hematopoietic progenitor cells are latently infected during primary CMV infection and thereafter serve as viral reservoirs. Furthermore, latently infected marrow progenitor cells are a likely vector for transmission of CMV infection by hematopoietic stem cell transplantation.

As CD33+ progenitors continue to differentiate they enter the peripheral blood. Monocytes appear to retain latent virus, but as they differentiate into macrophages CMV replication with production of progeny virus has been observed[35,79] (see Fig. 46–1). Cells of the monocytic lineage have been hypothesized to mediate transfusion-transmitted CMV, but the prevalence of latently infected monocytes in the peripheral blood appears to be low. It has been estimated that 0.004% to 0.01% of peripheral blood mononuclear cells (PBMCs) mobilized by granulocyte colony-stimulating factor[38] and 0.01% to 0.12% of PBMCs from healthy seropositive blood donors[35] contain CMV DNA, with a range of 2 to 13 viral genomes per infected cell.[38] Because approximately 5% of PBMCs are monocytes, latently infected monocytes may comprise only 1 to 25 of every million peripheral blood white blood cells (WBCs). The low numbers of latently infected leukocytes in transfused blood components may contribute to the variable incidence of transfusion-transmitted CMV observed clinically.

Cytomegalovirus is also found associated with other cell types in the peripheral blood and marrow. In immunocompromised patients with CMV infections, polymorphonuclear leukocytes (PMNs) phagocytose and contain large amounts of virus.[80] Although PMNs do not appear to support the complete viral replication cycle, they can retain CMV in a viable and infectious form under experimental circumstances.[81] CMV can also productively infect megakaryocytic precursors and mature megakaryocytes.[82] Plasma free virus appears to be less stable than intracellular virus, and the presence of free virus in plasma is usually transient.[83] For example, in one study of recently infected adolescents, only a minority (25% to 40%) had plasma viremia, which was rarely identified more than 4 months after seroconversion.[67] Based on the available evidence, these other peripheral blood sources of CMV are unlikely to be as important as latently infected monocytes to the pathogenesis of transfusion-transmitted CMV.

VIRAL LOADS

Quantitation of peripheral blood CMV load is clinically useful in immunocompromised patients, where viral loads can reach 10^8 copies per milliliter of plasma or greater,[84] and correlate with the severity of viral disease.[85–90] For example, in liver transplant recipients a 50% probability of CMV disease was associated with a viral load of $10^{5.1}$ genomes/mL of blood, and a 90% probability with $10^{5.5}$ genomes/mL.[87] Infectious virus can also be cultured readily from the blood of immunocompromised patients with active infections.[91]

In contrast, the peripheral blood viral load in CMV-infected but otherwise healthy individuals is much lower and rarely quantitated. For example, in a series of published studies CMV could be cultured from only 2 of over 1500 buffy coat samples from healthy blood donors.[70,92,93] Nonetheless,

a consideration of CMV loads in healthy individuals who are potential blood donors is useful in understanding the biology of transfusion-transmitted CMV (Fig. 46–2). WBC-associated viremia is often detectable for 6 months after infection,[67,94] in contrast to plasma free virus, which often disappears by 4 months. In recently seroconverted adolescents, 75% to 80% of WBC samples were positive for CMV DNA by PCR within the first 4 months of infection, compared with 25% to 40% of plasma samples within this same period.[67] A study of 98 seroconverting blood donors likewise identified a low frequency of transient plasma viremia.[83] In recently infected pregnant women, WBC-associated CMV DNA was detected in 100% of samples during the first month of infection using PCR and in 90% of samples during the second month of infection. None of the samples were positive after 6 months of infection.[94] WBC-associated viral load decreased substantially during early infection. During the first month 60% of positive samples had viral loads of more than 10 CMV genome-equivalents (GE)/10^5 WBCs (range of 10 to 398), whereas only 3.3% of positive samples during the second month of infection had more than 10 GE/10^5 WBCs.[94] Thus, shortly after infection of the immunocompetent host, the patient's viral load peaks. The subsequent decline in viral load correlates with the development of host anti-CMV immunity.

Host Immune Response

HUMORAL IMMUNITY

CMV infection initiates both a humoral and cellular immune response in the host, although anti-CMV antibodies exert limited control over CMV infection and disease. Antibody expression is typical of other humoral responses, with transient anti-CMV IgM synthesis followed by persistent expression of antiviral immunoglobulin G (IgG) (see Fig. 46–2). In a study of recently infected adolescents, anti-CMV antibodies were usually detectable by 6 to 8 weeks postinfection, a time of high peripheral blood viral loads.[67] However, despite the fact that anti-CMV, anti-gB, as well as viral neutralizing antibodies could be detected during the humoral response, they were insufficient to produce a precipitous decline in CMV DNA in either the plasma (free virus) or WBCs. Plasma and WBC-associated viral DNA were present in 25% to 40% and 75% to 80% of individuals, respectively, during the first 16 weeks of infection, and could still be detected in some individuals at 48 weeks of infection. Development of an antibody response likewise failed to immediately suppress viral shedding because CMV could be isolated from 59% of urine specimens during the first 80 weeks of infection.[67] Consistent with these observations, infectious virus has also been identified in saliva and cervical secretions of remotely infected seropositive individuals.[95,96] These findings indicate that anti-CMV antibodies, including those with neutralizing activities in vitro, may not completely prevent viral infectivity in vivo.

Nonetheless, anti-CMV antibodies can protect against sequelae of CMV infections in some circumstances. In a study of neonatal CMV infection, 10 of 10 (50%) infants born to seronegative mothers who subsequently contracted transfusion-transmitted CMV developed serious or fatal CMV disease. In contrast, 32 infants born to seropositive mothers contracted CMV infections, but none developed CMV disease, suggesting that passively acquired maternal CMV antibodies abrogated disease severity.[97] Therapeutic administration of antiviral antibodies, such as those present in intravenous immunoglobulin (IVIg) preparations, can also be efficacious in altering CMV disease course in some circumstances.[98]

Although anti-CMV antibodies generated during natural infection display a spectrum of specificities, among the more important targets is viral gB. Radioimmunoprecipitation assays using recombinant gB demonstrated the presence of anti-gB antibodies in the serum of all 48 seropositive donors tested.[99] Furthermore, the anti-gB antibodies were a significant component of the CMV-neutralizing activity in the serum samples. When anti-gB antibodies were absorbed with recombinant gB protein, viral neutralizing titer in the serum was reduced an average of 48%.[99] Similarly, other studies have demonstrated that 40% to 88% of serum CMV-neutralizing activity in naturally infected donors is directed against gB.[100,101] These results lend support for the use of recombinant gB as a subunit CMV vaccine.

CELLULAR IMMUNE RESPONSE

Cellular immune responses play an important role in the control of CMV infection. In bone marrow transplant (BMT) recipients, a patient population at high risk for CMV infection, development of a class I HLA-restricted CD8+ cytotoxic T-lymphocyte (CTL) response to CMV was significantly associated with the effective control of CMV infections.[102–106] In a study of 58 allogeneic BMT recipients with low or absent anti-CMV CTL activity at enrollment, 43 developed CMV infections, which were lethal in 12 of the patients.[102] Detectable anti-CMV CTL activity developed in all survivors of CMV infection, but in only 2 of the 12 patients

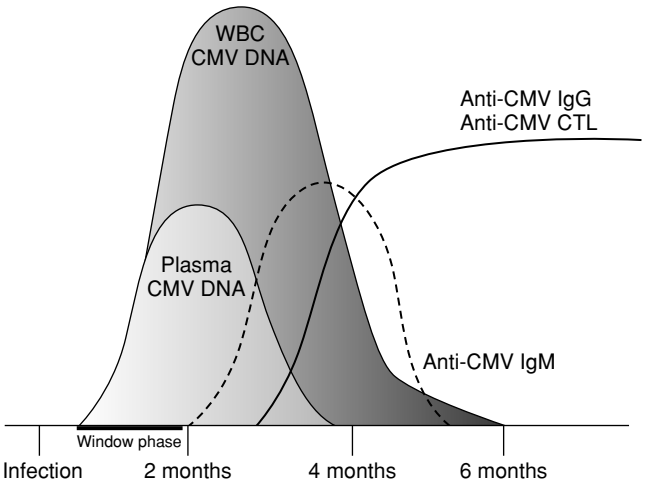

Figure 46–2 Temporal relationships between detection of plasma and white blood cell (WBC)-associated cytomegalovirus (CMV) DNA and the development of an immune response after primary infection. CMV DNA can be detected by polymerase chain reaction in both the plasma and WBC peripheral blood compartments during the first month of infection, and subsequently declines to undetectable levels over 4 to 6 months. The curves are not meant to be quantitative, but rather to illustrate that WBC-associated virus is more frequently detectable than plasma CMV during primary infection and also persists for a longer time. A humoral response is usually detectable by 8 weeks postinfection, and persists indefinitely, along with a cytotoxic T-lymphocyte response. The window phase represents the period between the initial presence of CMV in the peripheral blood and the first serologic evidence of CMV infection. Seronegative blood components obtained from donors in the window phase may explain some episodes of breakthrough transfusion-transmitted CMV in patients transfused exclusively with seronegative blood. See text for detailed discussion.

who succumbed to CMV disease. NK cell activity was also depressed in the patients with fatal CMV infection but not in those who controlled their infections.[102,103] In another study, 10 of 20 recipients of allogeneic BMT developed CMV-specific CTL activity by 3 months post-transplantation. Six of the 10 patients who failed to develop anti-CMV CTL activity died of CMV pneumonitis, and all 10 patients with a detectable CMV CTL response were protected.[104] Similar conclusions regarding the protective effects of CMV CTLs were reached with CMV-seropositive patients who underwent autologous peripheral blood stem cell or bone marrow transplantation. In these patients, whose preexisting CMV-specific CTLs were suppressed by the preparative regimen, the reappearance of anti-CMV CTL activity was positively correlated with control of CMV infections ($p = 0.002$).[105] The investigators also noted that a CD4 T-helper cell response to CMV always preceded the reappearance of anti-CMV CTLs, and appeared to be obligatory for the CTL response.[105,106]

Using a murine model, investigators specifically depleted CD4+ and CD8+ T cells from the animals before experimental CMV infection to determine the contribution of each subset to antiviral immunity. These studies showed that CMV-primed CD8+ CTLs were capable of controlling CMV infections in the absence of CD4+ cells, except in salivary glands.[107,108] Furthermore, the mice deficient in CD4+ cells did not make high levels of anti-CMV antibodies, indicating that when the antiviral CTL response is intact a humoral response is unnecessary for effective control of CMV infection.[107] In the murine model, NK cells are also important for control of acute CMV infection.[64,109] IFN-γ production appears to be one of the principal mechanisms through which CD8+ and NK cells exert this effect.[109–114] The observation that cellular immunity plays a critical role in controlling CMV infection has led to successful early-stage clinical trials in which CMV-immune CTLs were adoptively transferred into immunocompromised BMT recipients.[115]

Laboratory Diagnosis of CMV Infection

Accurate detection of CMV infection enables the identification of transfusion recipients at risk for CMV infection, as well as blood donors whose components are potentially infectious. Furthermore, quantitation of the degree of viral replication is important for guiding appropriate use of antiviral therapies, such as ganciclovir, cidofovir, and foscarnet, in immunocompromised patients. The standard approach for identifying a previously infected individual is through detection of anti-CMV antibodies (Table 46–2). Serologic assays have been developed in multiple configurations, including indirect hemagglutination, complement fixation, solid phase fluorescence immunoassay, enzyme immunoassay (EIA), latex or particle agglutination, and solid phase red cell adherence, although the first three of these techniques are no longer frequently used.[116–120] These assays detect anti-CMV antibodies of the IgG, and in some cases IgM and IgA, classes. Direct comparisons of the sensitivities and specificities of the latter four methodologies are difficult to perform owing to the lack of good standards. Some EIAs have stated sensitivities and specificities of approximately 99% and because of their objective readouts may have advantages over techniques such as latex agglutination. However, anti-CMV antibodies may not be detected by serology until 6 to 8 weeks after primary infection,[67] and serology cannot accurately identify or quantitate the extent of active CMV infection. Although viral culture can be used for these purposes, conventional tube cultures can require 2 weeks or more to yield results, and the more recently implemented shell vial methodology may still require 24 to 48 hours to detect the presence of infectious CMV.[121,122] Furthermore, these assays are only quantitative in a limiting-dilution format, which is labor intensive and not suited to routine clinical use.

The CMV antigenemia assay (which uses immunostaining to identify and quantitate peripheral blood leukocytes that contain CMV proteins) and CMV PCR have solved some of these problems.[123–127] The antigenemia assay can be used for both viral diagnosis and surveillance. Significantly, this methodology is sensitive enough for early quantitative detection of CMV infections, allowing the institution of preemptive (presymptomatic) antiviral therapies.[128,129] Qualitative PCR allows even earlier detection of CMV infection than does antigenemia.[86,130–132] However, due to its sensitivity, in some earlier studies PCR displayed poor positive predictive value for identifying patients at risk for CMV disease because some patients with low but detectable viral loads did not develop disease.[86,129,131] The recent introduction of quantitative PCR assays for CMV may provide a more rapid, sensitive, and specific predictor of patients at risk for CMV disease.[133] For example, the results obtained with a moderately sensitive (400 copies of CMV DNA/mL) quantitative CMV PCR assay strongly correlated with results from the antigenemia method and with development of CMV disease.[134] Advantages of the PCR method included reduced turnaround time, smaller sample requirements (200 µL plasma versus 3 to 5 mL blood), simplified specimen processing, improved stability of specimens before processing, and ability to test samples from patients with leukopenia.

Table 46–2 Routine Diagnostic Laboratory Methods for CMV

Method	Rapid	Quantitative	Detects Active Infection	Detects Latent Infection	Differentiates Active from Latent Infection
Serology	++	No	Yes	Yes	No
Culture	No	No	Yes	No	Yes
Antigenemia	+	Yes	Yes	No	Yes
PCR	++	Yes*	Yes	Yes	Yes*

++, < 6 hours turnaround time.
+, < 24 hours turnaround time.
*Depending on assay; see text for details.
PCR, polymerase chain reaction.

Turnaround time for PCR testing may be reduced even further by adopting assays to the real-time format.[84] Alternative nucleic acid testing methodologies, such as nucleic acid sequence-based amplification of CMV IE mRNA, may also be useful in CMV diagnosis.[135,136]

Transfusion-Transmitted CMV Infections

Background

By the mid-1960s, a number of investigators had described an illness with clinical similarities to infectious mononucleosis occurring in patients who were exposed to blood products during cardiopulmonary bypass for open-heart surgery.[137,138] Patients typically presented with fever, splenomegaly, and atypical lymphocytosis within 3 to 8 weeks of surgery, but had a negative heterophile antibody test and did not experience exudative pharyngitis or lymphadenopathy. Klemola and Kaariainen subsequently demonstrated an increase in the titer of complement-fixing anti-CMV antibodies concurrent with the illness, suggesting that the etiology was CMV infection acquired from transfused blood products.[139,140] Further support for this hypothesis was provided by culturing CMV shed into the urine or blood of patients experiencing what was then called *cytomegalovirus mononucleosis.*[141] In the ensuing years, the disease has come to be known as *transfusion-transmitted cytomegalovirus infection* and has been described in a wide variety of clinical circumstances, although it is of most significance in immunocompromised transfusion recipients.[142–147] In most cases the diagnosis of transfusion-transmitted CMV is correlative: evidence of primary CMV infection in a previously seronegative patient who received a cellular blood component (red cells, platelets, or granulocytes) that was neither CMV-seronegative nor filtered. However, in at least one instance unequivocal molecular evidence for transfusion-transmitted CMV was provided by demonstrating identical restriction endonuclease digestion patterns of CMV isolates from a seropositive blood donor and from the neonates who were transfused with his blood component and subsequently developed CMV infection.[148]

Transfusion can lead to active CMV infection in the recipient by three mechanisms. The term *transfusion-transmitted CMV* is used to describe a primary CMV infection occurring in a seronegative recipient transfused with an infectious blood component. In contrast, *reactivated CMV infection* can occur when a seropositive transfusion recipient experiences reactivation of their latent CMV infection after blood transfusion from a seronegative donor. The mechanism underlying reactivated CMV infection likely involves immunomodulatory interactions between MHC mismatched leukocytes of the donor and recipient. Consistent with this mechanism, studies indicate that the incidence of CMV reactivation is independent of donor serostatus and component storage time, but increases with the volume of blood transfused.[149,150] Finally, *CMV superinfection* (second-strain infection) occurs when a seropositive recipient contracts a new strain of CMV from an infectious blood component. The diagnosis of both reactivation and superinfection is based on a fourfold or greater rise in the titer of anti-CMV antibodies and/or renewed viral shedding in secretions of seropositive transfusion recipients.[70] Although reactivation and superinfection can be distinguished from one another by restriction endonuclease genotyping of CMV strains,[151] this analysis has no significant clinical implications. These three mechanisms of transfusion-associated CMV infection appear to occur with similar frequencies. A review of five early studies of transfused CMV-seropositive patients calculated a 26% cumulative incidence of CMV reactivation or superinfection (66 of 252 patients), compared to a 31% incidence (99 of 323) of transfusion-transmitted CMV in seronegative recipients reported in seven contemporary studies (reviewed in Adler[70]). Nonetheless, the clinical significance of transfusion-transmitted CMV overshadows that of CMV reactivation and superinfection because transfusion-transmitted CMV results in a primary infection against which the recipient has no preexisting immunologic memory. In contrast, CMV reactivation and superinfection are unlikely to cause morbidity in the transfusion recipient.[152] Finally, it should be noted that although most cases of suspected transfusion-transmitted CMV result from the transfused component,[153,154] a minority of cases may result from community-acquired CMV infection occurring in temporal proximity to the transfusion.

Patients at Risk and Incidence

Although transfusion-transmitted CMV produces a primary CMV infection, in the immunocompetent transfusion recipient it is of no more clinical significance than community-acquired CMV infection. Furthermore, the risk of transfusion-transmitted CMV is very low in these patients. Early studies showed that 1.2% or fewer of immunocompetent patients experienced transfusion-transmitted CMV.[155,156] In a more recent study of 76 seronegative children with malignancies, there were no cases of transfusion-transmitted CMV in patients who received either seronegative or unscreened units, resulting in a calculated risk of less than 1 in 698 donor exposures in this population.[157] It should be noted that for reasons unrelated to study design, some of the units transfused in this study were washed or filtered. Follow-up of these children revealed that 2 of 76 subsequently developed community-acquired CMV infections (1.7% per patient-year), demonstrating the relatively greater incidence of community-acquired CMV infections than transfusion-transmitted CMV in this immunocompetent population. Furthermore, even in one early study where 32% of nonimmunosuppressed patients undergoing tumor resection developed transfusion-transmitted CMV, there was no evidence of CMV disease.[149] Thus, at present there are no compelling reasons to provide nonimmunosuppressed seronegative transfusion recipients with special components for the purposes of preventing transfusion-transmitted CMV.

In contrast, transfusion-transmitted CMV can be an important cause of morbidity and mortality in immunocompromised patients (Table 46–3). Most studies suggest that 13% to 37% of these patients will contract CMV from transfusion of unscreened and unfiltered cellular blood components.[97,158–161] The most well-established patient groups at risk for transfusion-transmitted CMV include premature low-birth-weight infants (<1250 to 1500 grams) born to seronegative mothers, seronegative recipients of seronegative allogeneic or autologous BMT, seronegative recipients of seronegative solid organ transplants, and seronegative patients with AIDS.[145,147,162] In these patients, the first manifestations of transfusion-transmitted CMV are often a viral syndrome, characterized by a flulike illness, including fever, chills, malaise, leukopenia, thrombocytopenia, and mild abnormalities

Table 46–3 **Patients at Risk for Transfusion-Transmitted CMV**

Category A: Clear morbidity and mortality from transfusion-transmitted CMV; CMV-safe components proven efficacious in decreasing incidence of transfusion-transmitted CMV, and should be used for all transfusions.
- Low-birth-weight infants (<1500 grams) of seronegative mothers
- Seronegative recipients of autologous or seronegative allogeneic bone marrow transplantation
- Seronegative recipients of seronegative solid organ transplants, excluding renal and cardiac

Category B: Identified risk of morbidity and mortality from transfusion-transmitted CMV; benefit of CMV-safe products is possible or likely, but not proven; consider using CMV-safe components when availability allows.
- Seronegative pregnant women requiring antepartum blood transfusion or intrauterine transfusion
- Seropositive women requiring intrauterine transfusion
- Low-birth-weight infants or seronegative immunosuppressed patients requiring granulocyte transfusions
- Seronegative HIV-infected patients
- Children born to HIV-infected mothers
- Low-birth-weight infants of seropositive mothers
- Seronegative patients who may be candidates for bone marrow transplantation

Category C: Morbidity and mortality of transfusion-transmitted CMV low or poorly documented, but likely greater than Category D; consider CMV-safe products on a case-by-case basis.
- Infants with birthweight > 1500 grams, born to seronegative mothers
- Neonates receiving ECMO or extensive transfusion support (e.g., exchange transfusions)
- Seronegative recipients of seronegative renal or cardiac transplantation
- Seronegative patients receiving chemotherapy
- Seronegative patients experiencing major trauma or splenectomy

Category D: Low morbidity and mortality of transfusion-transmitted CMV; CMV-safe components not indicated.
- Infants with birthweight > 1500 grams, born to seropositive mothers
- All other transfusion recipients not listed above

Modified with permission from Preiksaitis JK. The cytomegalovirus-"safe" blood product: Is leukoreduction equivalent to antibody screening? Transfus Med Rev 2000;14(2):112–136.

in liver function tests. The illness can progress to disseminated tissue-invasive CMV disease, including CMV hepatitis, retinitis, interstitial pneumonitis, encephalitis, and gastroenteritis, including esophagitis.[163] Progression to disease is more likely in patients with elevated viral loads. CMV infections are also associated with, and may predispose to, other complications in immunocompromised patients, including graft-versus-host disease (GVHD) in allogeneic marrow transplant recipients,[164–166] accelerated solid organ graft rejection,[167,168] and other opportunistic infections, including invasive fungal disease.[163,169]

Seronegative infants transfused with unscreened blood products had a 13.5% incidence of transfusion-transmitted CMV.[97] When greater than 50 mL of packed red cells were transfused, the incidence of transfusion-transmitted CMV increased to 24%. Of the infants who acquired transfusion-transmitted CMV, five (50%) developed serious symptoms or fatal disease, all of them weighing less than 1200 grams.[97] In other studies, seronegative neonates weighing less than 1250 to 1500 grams also experienced a high incidence of transfusion-transmitted CMV (reviewed in Preiksaitis[170]), likely due to their immature immune systems. It should be noted, however, that low-birth-weight infants born to seropositive mothers can also be at risk for lethal CMV infection, despite the transfer of humoral immunity.[171]

Marrow transplant recipients are at significant risk of morbidity and mortality from CMV infections. Up to one third of those patients who contract CMV infection can develop CMV pneumonitis, a frequently fatal complication.[172] In seropositive marrow recipients, CMV infection is usually due to viral reactivation, making CMV seropositivity the most important risk factor for CMV infection and disease.[172–175] CMV infection also occurs frequently in seronegative recipients of seropositive marrow.[158–160] However, in seronegative recipients of seronegative marrow or autologous transplants, transfusion is the primary mechanism for CMV infection.[158–160] Solid-organ transplant recipients are also susceptible to CMV infection and disease. In contrast to marrow transplantation, the most important source of CMV infection is the donor organ, with transfusion-transmitted CMV being less significant.[144,176–179] In seronegative recipients of seronegative organs, transfusion of unscreened blood products has been associated with an incidence of CMV ranging from 0 to 33%, with a cumulative incidence of approximately 9% (reviewed in Roback[147] and Preiksaitis[170]). Among organ transplant recipients, those receiving heart, heart-lung, liver, and pancreas transplants usually require numerous transfusions and thus have an increased risk of transfusion-transmitted CMV. Early studies showed that even in heavily transfused organ transplant recipients, the use of seronegative blood products could effectively prevent transfusion-transmitted CMV.[180–182]

In addition to these patient populations with well-defined susceptibility to transfusion-transmitted CMV, there are other groups that may be susceptible and may also benefit from transfusion of CMV-safe blood components (see Table 46–3). For example, it is well-documented that primary CMV infection during pregnancy carries high risks of congenital fetal infection. Although there is no direct evidence that primary maternal infection resulting from transfusion-transmitted CMV can in turn lead to fetal infection,[68,156] it is prudent to provide CMV-safe blood components to pregnant women who are seronegative. Because of the high incidence of CMV reactivation and infection in seropositive marrow recipients, 69% in one study,[172] transfusion-transmitted CMV is not a significant concern in these patients. However, special components may be considered for seronegative patients who are candidates for BMT, including

immunosuppressed oncology patients, to prevent infection before transplant.

Blood Components Implicated in Transfusion-Transmitted CMV

Most evidence suggests that the primary vector for transfusion-transmitted CMV is the CMV-infected leukocyte (Table 46–4). Transfusion-transmitted CMV has not been observed in patients receiving blood components that are free of WBCs, arguing that plasma free virus is not significantly involved in the pathogenesis of transfusion-transmitted CMV.[183] For example, there was no evidence of transfusion-transmitted CMV in a group of 21 immunosuppressed seronegative recipients of seronegative BMT undergoing total plasma exchange, although they were exposed to an average of 47.6 +/− 19.5 units of unscreened fresh frozen plasma (FFP).[184] The absence of CMV after transfusion of FFP may be due to the scarcity of plasma free virus in healthy seropositive donors, as well as neutralization of virus by anti-CMV antibodies.

In contrast, there is an abundance of evidence that transfusion-transmitted CMV can be mediated by WBCs in blood components and that the incidence of transfusion-transmitted CMV correlates with the WBC load. For example, multiple studies have demonstrated transfusion-transmitted CMV after granulocyte transfusions, most often by seropositive granulocyte preparations transfused to seronegative recipients.[154,172,185] Red blood cell and platelet transfusions are also known to transmit CMV infections[97] (see Table 46–4).

Comparison of data over the past 4 decades reveals a correlation between decreased usage of fresh blood since the 1960s and a decline in the incidence of transfusion-transmitted CMV produced by unscreened units over the same period.[186] Most early evidence suggested that fresh blood (donated within 24 hours) from seropositive donors was more infectious than stored blood.[145,155] For example, in the initial descriptions, transfusion-transmitted CMV typically occurred following open-heart surgery in which the patient was exposed to fresh whole blood.[138–140] In nonimmunosuppressed seronegative transfusion recipients, 6 of 7 patients who seroconverted were transfused with fresh whole blood. In contrast, among 585 patients who did not seroconvert, only 53 had received fresh blood ($p < 0.001$).[155] Similar findings were made in a pediatric study where transfusion-transmitted CMV occurred in 13 of 15 children (87%) who received fresh blood (<24 hours old) as compared to 1 of 6 children (17%; $p = 0.01$) receiving blood more than 24 hours old.[161] In the same study, none of the children receiving only CMV-seronegative blood developed CMV, compared to the 36% rate of CMV in children receiving unscreened blood.[161] Overall, the infection rate with transfusion of fresh blood has been documented at 10% to 59% (reviewed in Lee and coworkers[161]). A decline in infectivity with storage has also been shown experimentally. When naturally infected blood obtained from AIDS patients with CMV viremia was refrigerated under standard conditions, CMV infectivity was rapidly lost during the first 5 days of storage.[187] However, not all studies have demonstrated an effect of product storage interval on the incidence of transfusion-transmitted CMV.[70,149,153,188]

It is also useful to consider the percentage of donated blood components that can transmit CMV infection. In a review of 10 studies published between 1968 and 1988, including data from 2806 patients, Ho calculated the changing risk of contracting transfusion-transmitted CMV over this period.[186] The risk per unit of unscreened and unfiltered blood was calculated at 11% to 12% in 1968 to 1970, and remained at greater than 1% per unit until the early 1980s. However, the risk subsequently fell to 0.4% or less by 1988.[186] Possible reasons for changes in the epidemiology of transfusion-transmitted CMV include decreasing use of fresh blood, improved tools for CMV serologic screening of blood donors and recipients, implementation of improved protocols to screen for other viral infections, and exclusion of blood from homosexual men starting in the mid-1980s.[186] The risk of transfusion-transmitted CMV also varies with different groups of transfusion recipients. In studies where recipients were immunosuppressed, 2.5% to 12% of unscreened blood components were estimated to be infectious.[70,97,144] Adler estimated that although 5% of all units were capable of producing CMV infection, 15% of seropositive units were potentially infectious.[189] In nonimmunosuppressed patients, in contrast, the risk may be as low as 0.14% of randomly selected units, or 0.38% of seropositive units.

Pathobiology of Transfusion-Transmitted CMV Infections

Clinical evidence for the involvement of leukocytes in transfusion-transmitted CMV include the observations that CMV is transmitted with high frequency by granulocyte transfusions from seropositive donors,[154] whereas the incidence of transfusion-transmitted CMV can be attenuated by removing leukocytes from blood components.[146,190] Furthermore, these WBCs are in almost all cases latently infected. When more than 1500 buffy coat samples from healthy blood donors were subject to viral culture in multiple studies, only 2 samples (both seropositive) grew infectious CMV.[70,92,93] These results demonstrate that when WBC-associated CMV is present, it is nearly always in the latent state. Experimental studies have indicated that WBCs of the monocyte lineage are

Table 46–4 **Component-associated Risk of Transfusion-Transmitted CMV**

Blood Component	Transfusion-Transmitted CMV Risk?	Processing to Abrogate Transfusion-Transmitted CMV
Red cells	Yes	Screening, filtration, frozen-deglycerolized
Platelets	Yes	Screening, filtration
Granulocytes	Yes	Screening
Fresh frozen plasma	No	n/a
Cryoprecipitate	No*	n/a
Clotting factors	No	n/a

*Not specifically tested, but other plasma-derived components have not been shown to be infectious for CMV.
n/a, not applicable.

the most likely to carry latent CMV in seropositive donors,[36] and thus are likely to be of most importance for transfusion-transmitted CMV (see Fig. 46–1). Circulating latently infected monocytes must be able to support viral reactivation from latency to mediate transfusion-transmitted CMV. Cultured monocytes can be differentiated in vitro into multinucleated giant cells by exposure to allogeneic cells. The degree of differentiation has been positively correlated with levels of CMV replication.[191] Latently infected monocytes and CD33+ bone marrow cells became permissive for CMV reactivation and viral replication after exposure to T-cell conditioned medium and hydrocortisone[192] or the combination of IFN-γ, tumor necrosis factor α, and interleukin-4, respectively[36] (see Fig. 46–1). When monocytes from healthy seropositive donors were grown in a mitogen-stimulated culture system containing allogeneic adherent mononuclear cells, the resulting differentiated monocyte-derived macrophages initiated production of infectious CMV.[35] These studies demonstrate that naturally infected peripheral blood monocytes contain latent CMV and that exposure to allogeneic cells or appropriate cytokine milieus such as would be encountered in transfusion recipients renders them permissive to viral reactivation with production of infectious CMV[36] (see Fig. 46–1).

There may also be additional factors, including recipient-related mechanisms, that modulate the incidence and severity of transfusion-transmitted CMV.[68] For example, as compared to immunologically competent transfusion recipients, immunocompromised patients have higher rates of transfusion-transmitted CMV and CMV diseases, including retinitis, esophagitis, and interstitial pneumonitis.[72,146] Even among immunocompromised patients there are factors that can affect the recipient's susceptibility to CMV infection and disease. In recipients of cadaveric renal transplants who were at risk for CMV infection, the immunosuppressive regimen employed significantly influenced survival.[193] The development of GVHD affects the incidence of CMV infection and disease in BMT recipients.[172,173] In a study of 181 recipients of allogeneic BMT, CMV infections occurred in 34 of 81 who developed acute GVHD as compared to 20 of 100 who did not ($p < 0.001$). Of the 34 patients who developed both CMV infection and GVHD, diagnosis of GVHD preceded the onset of CMV infection by a mean of 33.7 days, suggesting that GVHD predisposed to CMV infection.[175] A comparison of seronegative recipients of either autologous or seronegative allogeneic BMT showed that both groups had similar rates of transfusion-transmitted CMV, but the incidence of CMV interstitial pneumonitis was significantly greater following allogeneic transplantation, particularly if the allogeneic recipients developed GVHD.[164–166] Preiksaitis has recently suggested that the following factors may also predispose to transfusion-transmitted CMV: sequential transfusion over a long period of time as compared to large transfusion volumes given at one time, the use of HLA-matched donors, repetitive transfusions from the same donor, and the degree of immunosuppression and cytokine expression profile in the host.[68] However, the biologic variables potentially affecting transfusion-transmitted CMV are difficult to dissect in the clinical setting and will likely be more amenable to investigation in experimental models. For example, a murine model of transfusion-transmitted CMV has been developed in which the incidence of transfusion-transmitted CMV is affected by viral load and MHC mismatches between blood donor and recipient.[194,195]

Prevention of Transfusion-Transmitted CMV

The incidence of transfusion-transmitted CMV, as well as that of other untoward effects of transfusion, can be reduced by limiting transfusions to appropriate, clinically indicated circumstances. However, when transfusions are necessary, the most common approaches to decrease the risk of transfusion-transmitted CMV are the use of CMV-seronegative or filtered components (see Table 46–4). Nonetheless, it is clear that there remains a small residual risk of transfusion-transmitted CMV associated with the use of either type of component.[190]

SERONEGATIVE BLOOD COMPONENTS

Multiple studies, including prospective randomized, controlled trials, have demonstrated that exclusive use of CMV-seronegative units for transfusion can decrease the incidence of transfusion-transmitted CMV, as compared to use of unscreened units.[97,155,158,160,161,196] An early study of newborn infants demonstrated that none of 90 seronegative infants transfused with seronegative components contracted CMV infections, as compared to 13.5% of seronegative infants receiving transfusions from seropositive donors.[97] The exclusive use of seronegative units in immunocompromised adult seronegative recipients of allogeneic seronegative BMTs also decreased the incidence of CMV and severity of resulting CMV disease as compared to the use of unscreened blood products.[160] However, the use of seronegative units was only beneficial in seronegative recipients of seronegative donor marrow. Seronegative recipients of seropositive marrow transplants had a 46% incidence of CMV infection when transfused with unscreened blood, which was not significantly different from the 32% incidence when these patients received seronegative blood products.[160] The absence of a beneficial effect of seronegative transfusions for seronegative recipients of seropositive marrow was also observed in another study.[158] In nonimmunosuppressed seronegative patients, transfusion of seronegative blood components can also prevent transfusion-transmitted CMV,[155] although there are few indications for use of seronegative blood in this population. Based on these and other data, seronegative units remain the gold standard for the prevention of CMV in susceptible transfusion recipients (see Table 46–4).

Despite exclusive use of seronegative units for transfusion, up to 4% of susceptible recipients have acquired CMV.[158,160,190] False-negative donor serology may have contributed to some of these cases of breakthrough transfusion-transmitted CMV, particularly in studies using earlier generation serology assays.[157,196] Even sensitive and specific assays that detect anti-CMV antibodies of IgG, IgM, and in some cases IgA classes can show significant disagreement when applied to samples from blood donors.[69] Alternatively, some donors may have been in the 6- to 8-week *window-phase* following primary CMV infection, during which anti-CMV antibodies cannot be detected reliably[67] (see Fig. 46–2). During this period there are high peripheral blood viral loads,[67] suggesting that transfusions from these "seronegative" donors may be infectious. Detection of anti-CMV antibodies of the IgM class early during the course of infection appears to be important for preventing transfusion-transmitted CMV.[197] In one study, patients who received components with detectable IgM anti-CMV antibodies had a CMV infection rate of 8.4% (7 of 83 recipients) compared to a rate of 0.3% (1 of 280 patients; $p < 0.001$) in those who received

blood without IgM anti-CMV.[198] Interestingly, in this study only 1 of 163 neonates who received seropositive, but IgM-negative, blood developed CMV.[198] However, other investigators have found that screening for IgM anti-CMV antibodies had poor sensitivity and specificity for identifying infectious blood components.[68]

FILTERED BLOOD COMPONENTS

The seroprevalence rate for CMV ranges from 40% to 80% in the United States.[4,69,72] The difficulties in maintaining a sufficient inventory of CMV seronegative blood components motivated efforts to identify alternative strategies to provide CMV-safe components for susceptible patients. Because WBCs latently infected with CMV are the primary vector for transfusion-transmitted CMV, removal of WBCs from components was an attractive approach to mitigate transfusion-transmitted CMV. Current third-generation filtration technology can produce a 3 to 4 $\log_{10}$ reduction in monocytes and other leukocytes in blood components.[199] Alternatively, platelets and red cells can be prepared from donors by apheresis procedures, resulting in process-leukoreduced components with 10^5 to 10^6 residual leukocytes, depending on instrumentation and separation technique.[200] This level of leukoreduction has been shown to significantly reduce the incidence of transfusion-transmitted CMV in multiple studies.[146,159,201–204] In the largest prospective, randomized, controlled clinical trial to address this issue to date, Bowden and colleagues randomized 502 seronegative recipients of autologous or seronegative allogeneic BMT to receive either unscreened blood products filter-leukoreduced at the bedside or CMV-seronegative components.[190] Between 21 and 100 days post-transplantation, the predefined window phase for identifying transfusion-transmitted CMV, the probabilities of developing CMV infection were similar in patients receiving filtered units (2.4%) and those receiving seronegative components (1.3%; $p = 1.00$). The probabilities of developing CMV disease were also similar in these two groups (2.4% vs 0%, respectively; $p = 1.00$). Based on an intention-to-treat analysis, the authors concluded that seronegative and filtered units carried equivalent risks of transfusion-transmitted CMV. The interpretation of this study was complicated by an analysis of all data from days 0 to 100 that showed a statistically greater progression to CMV disease in the group receiving filtered components as compared to those receiving seronegative components (2.4% vs 0%, respectively; $p = 0.03$). In fact, five of six patients who contracted CMV from filtered units developed CMV disease that progressed to fatal CMV pneumonia, whereas none of four patients infected with CMV from seronegative components developed CMV disease ($p = 0.005$ by Fisher's exact test).[190,205] The biologic basis for this difference remains unexplained,[205,206] leaving open the possibility that there are differences between filtered and seronegative units with respect to the risk of transfusion-transmitted CMV. However, it should be noted that this study utilized bedside filtration, which is unlikely to produce the degree and reproducibility of leukoreduction achievable with prestorage filtration methods. A more recent large retrospective study also showed an increased incidence of transfusion-transmitted CMV in patients who received leukoreduced products.[207] Weekly surveillance for the presence of CMV viremia was performed on a cohort of 807 CMV-seronegative stem cell transplant recipients, demonstrating a significant increase in the incidence of transfusion-transmitted CMV when seronegative units were partially replaced by filtered blood components. In particular, the use of filtered red blood cell units was positively associated with an increase in CMV infection.[207] In a recent review, Preiksaitis provided a detailed discussion of the theoretical and observed differences between the use of CMV-seronegative units and filtered units.[68]

OTHER COMMON COMPONENT PROCESSING METHODOLOGIES

In seronegative neonates, the exclusive use of frozen-deglycerolized red cells markedly reduces the incidence of transfusion-transmitted CMV, providing a third option along with seronegative and filtered components for patients at risk for CMV.[146,208,209] However, given the labor-intensive nature of preparing frozen-deglycerolized red cells, this approach is rarely used. In contrast, it is unclear whether washing of components can adequately decrease the incidence of transfusion-transmitted CMV. In one study of seronegative neonates, transfusion of washed red cells from seropositive donors was associated with a 1.3% incidence of transfusion-transmitted CMV,[210] below the historical incidence of 13% to 37%.[97,158–160] However, in another study transfusion of washed red cells resulted in an 11.1% incidence of CMV in seronegative neonates.[211] Given these conflicting data, together with the logistics of washing blood components, this procedure cannot be recommended for preparation of CMV-safe blood components. Likewise, standard gamma-irradiation protocols used to prevent transfusion-associated GVHD are not effective at abrogating transfusion-transmitted CMV.

IMMUNOGLOBULIN PREPARATIONS AND ANTIVIRAL DRUGS

The efficacy of passively acquired maternal anti-CMV antibodies to abrogate CMV infection and disease in neonates suggested that CMV immunoglobulin preparations may be useful in immunocompromised adults. In an early randomized trial of prophylactic hyperimmune CMV IVIg, BMT recipients receiving IVIg were protected against CMV infection ($p = 0.009$), interstitial pneumonia, and CMV mortality ($p = 0.014$) as compared to the control group.[212] Other studies have produced similar findings.[213] A meta-analysis derived from 12 published clinical trials of prophylactic IVIg in BMT patients confirmed that passive CMV antibodies could significantly reduce fatal CMV infection (95% confidence interval (CI), 0.23–0.99), CMV pneumonitis (CI, 0.42–0.89), non-CMV interstitial pneumonia (CI, 0.35–0.95), and total CMV mortality (CI, 0.55–0.99).[98] However, the efficacy of IVIg in preventing transfusion-transmitted CMV is more difficult to assess. For example, when seronegative study patients were transfused with seronegative blood, the current standard of care, there was no significant effect of IVIg on CMV infection and disease.[158] Furthermore, intramuscular CMV immune globulin was ineffective in preventing transfusion-transmitted CMV in seronegative patients who received seropositive granulocyte infusions.[214]

In allogeneic marrow transplantation, ganciclovir can provide effective prophylaxis against CMV disease.[215,216] However, ganciclovir can also cause untoward effects, including marrow suppression with neutropenia, delayed reconstitution of cellular immunity predisposing to opportunistic infections, and outgrowth of resistant viral mutants.[217–219] Even limited use of ganciclovir has caused severe neutropenia in 33% (10 of 30) of treated patients, 7 of whom subsequently developed opportunistic infections.[220] Furthermore, despite adequate control of CMV infections in these patients,

they experienced increased mortality due to other infectious complications, including *Aspergillus fumigatus*, *Streptococcus pneumoniae*, and *Pneumocystis carinii* pneumonia.[220] In a randomized, placebo-controlled trial of prophylactic ganciclovir in marrow transplant recipients, ganciclovir usage lead to delayed recovery of anti-CMV CTL activity, which may predispose patients to late-onset CMV disease.[106] Up to 15% of BMT recipients develop late CMV disease after discontinuation of ganciclovir prophylaxis,[215] and the mortality of late-onset disease approaches 70%.[106] Prolonged ganciclovir therapy can also lead to selection of drug-resistant CMV mutants. In one study, 38% (5 of 13) of AIDS patients treated with ganciclovir longer than 3 months shed resistant mutants.[221] Children receiving T cell–depleted marrow transplants also appear to be at increased risk for developing ganciclovir-resistant mutants, as well as strains resistant to the antiviral compounds foscarnet and cidofovir.[222] These concerns underscore the importance of preventing CMV transmission, rather than treating resulting CMV infections and disease.[223] Furthermore, when compared to the proven efficacy of seronegative or filtered units to decrease the incidence of transfusion-transmitted CMV, the use of IVIg and/or antiviral agents would be more expensive and possibly not as effective, and thus these interventions cannot be recommended for abrogation of transfusion-transmitted CMV.

NAT-SCREENED COMPONENTS

With standard serologic assays, both uninfected donors and those in the window phase of a CMV infection test as seronegative. Some window phase donors have high plasma and WBC-associated viral loads, and thus although seronegative their blood may be infectious on transfusion.[67,94] Blood components from most CMV-seropositive donors do not produce transfusion-transmitted CMV, but serologic testing is unable to distinguish these from infectious seropositive units. Filter leukoreduction decreases the incidence of transfusion-transmitted CMV but immunocompromised patients who acquire CMV from filtered blood can develop significant CMV-associated disease.[190] Thus, neither serologic screening nor leukoreduction produces a blood supply that is completely CMV-safe. In analogy with NAT screening for human immunodeficiency virus (HIV) and hepatitis C, NAT screening for CMV DNA may identify blood components that can produce transfusion-transmitted CMV and may serve as a useful adjunct to serology and filtration.

Because most seropositive donors are remotely infected (>6 months), they are likely to have peripheral blood viral loads near or below the limits of detection of even sensitive NAT assays. Assays sufficiently sensitive to detect these low viral loads may be subject to problems, including nonspecific amplification of background DNA. For this reason, it is not surprising that several studies investigating the presence of CMV DNA in healthy blood donors have yielded conflicting results. Some investigators have identified CMV DNA in WBCs or isolated monocytes from both seropositive and seronegative donors.[224–226] In a study of 270 healthy blood donors in Sweden, the use of nested PCR demonstrated CMV DNA in peripheral blood mononuclear cells from 14% of seronegative donors using both UL123 and UL32 PCR assays, although the CMV DNA detection rate increased to 55% if monocyte-enriched samples from seronegative donors were assayed.[227] These investigators also identified CMV DNA in 100% of seropositive donors. In contrast, other investigators have been unable or only rarely able to identify CMV by PCR in peripheral blood from seropositive or seronegative donors.[83,94,126,127,130,228–230] These latter findings appear more consistent with the clinical experience that seronegative blood components only rarely transmit CMV infections to transfusion recipients, and that only 0.4% to 12% of seropositive blood units appear capable of CMV transmission.[155,156,180] The variability of the results in these prior studies demonstrate that technical hurdles remain prior to implementation of CMV NAT for testing of the blood supply.

To identify CMV PCR assays with appropriate performance characteristics for screening healthy blood donors, a multicenter trial was undertaken to determine the sensitivity, specificity, and reproducibility of seven previously described assays.[231] In practice, the DNA yield from 250,000 WBCs (approximately 2 μg of DNA) is the maximum tolerated input for most PCR assays. Based on estimates that 0.004% to 0.12% of PBMCs are latently infected,[35,38] it was predicted that an average of 4 to 120 latently infected cells would be present per 250,000 WBCs (PBMCs typically comprise 40% of WBCs). Given the reported presence of 2 to 13 viral genomes per latently infected cell,[38] it was hypothesized that PCR assays used in donor screening should be sufficiently sensitive to detect 8 to 1560 CMV genome equivalents (GE) in 250,000 WBCs. Five of the examined assays displayed sufficient sensitivity for donor screening based on consistent detection of a minimum of 25 CMV GE in analytical controls constructed to contain from 1 to 100 CMV GE in background DNA from 250,000 cells.[231] Of these five assays, two detected CMV DNA in a subset of 20 pedigreed CMV seronegative samples. However, these results were found to be inconsistent when the seronegative samples were reanalyzed. The other three sensitive assays did not detect CMV DNA in the seronegative samples, and two of these were selected for further study. These assays, a nested PCR directed at the CMV UL93 ORF and the Roche Monitor assay, were used to screen 1000 blood samples from healthy donors.[69] Of the 416 seropositive donor samples, 2 (0.5%) tested positive for CMV DNA with both assays, and 7 other samples tested positive with only one assay and did not confirm on retesting. When the two positive samples were subjected to limiting dilution analysis they were found to have viral loads of 1 to 10 copies per 250,000 WBCs, demonstrating that CMV DNA loads in healthy blood donors are at or below the limits of detection of even sensitive PCR assays. Six of the seronegative samples tested positive with only one assay and were not confirmed on repeat testing. These results suggest that only a small percentage of seropositive samples from healthy blood donors have viral loads that are reproducibly detectable by extremely sensitive PCR assays, potentially limiting the use of PCR to prevent transfusion-transmitted CMV. It should be noted that the minimal viral load required for transfusion-transmitted CMV has not been determined, and it must be assumed at present that any CMV-seropositive or CMV DNA-positive unit is potentially infectious.

VIRAL INACTIVATION, CMV VACCINATION, AND ADOPTIVE IMMUNOTHERAPY TO DECREASE THE INCIDENCE OF TT-CMV

As opposed to current approaches such as the use of seronegative and filtered components, the application of pathogen inactivation technology to cellular blood components carries the potential for completely preventing transfusion-transmitted CMV, as well as eliminating

the transmission of other infectious agents. The psoralen derivative 8-methoxypsoralen (8-MOP), when exposed to ultraviolet light, can inactivate a spectrum of both gram-positive and gram-negative organisms that can contaminate platelet components, including *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, *Yersinia enterocolitica*, *Salmonella choleraesuis*, *Serratia marcescens*, and *Pseudomonas aeruginosa*.[232–234] Bacterial concentrations of 10^4 to 10^7 CFU/mL can be inactivated, which compares favorably with estimated bacterial concentrations of 10 to 10^3 CFU/mL in naturally infected units.[235] In vitro platelet function was not adversely affected by 8-MOP treatment. Similar results were obtained with another psoralen derivative, S-59, which could efficiently inactivate more than 10^6 plaque-forming units per milliliter of HIV, duck hepatitis B virus, and bovine diarrhea virus (a model for HCV) in experimentally infected platelet components.[236–238] S-59 also effectively prevented transfusion-transmitted CMV in a murine transfusion model.[195] Viral inactivation technology has entered clinical trials and is the subject of Chapter 27 in this volume.

Given the limited risk of transfusion-associated CMV disease in seropositive recipients, vaccination of seronegative patients prior to immunosuppression may mitigate the risks of CMV in this population. Use of an attenuated Towne CMV strain as a live virus vaccine in 237 renal transplant recipients demonstrated that vaccinated seronegative recipients of seropositive grafts had similar rates of infection to unvaccinated controls but experienced less severe disease. Furthermore, the survival of cadaveric renal grafts at 36 months was improved by vaccination compared with the control group ($p = 0.04$).[239] Although there were no episodes of Towne CMV reactivation following latency in these immunosuppressed patients, this possibility must be considered when evaluating the safety of this approach. The use of recombinant CMV proteins as subunit vaccines represents a potentially safer method of vaccination. In experimental settings, recombinant gB protein can induce protective immunity,[101] and anti-gB antibodies in naturally infected donors comprise a large component of the CMV-neutralizing activity in seropositive donor serum.[99,101]

Recovery of CMV-specific CTLs following marrow transplantation provides protection from CMV infection and disease.[102–104,106] However, at 40 days post-transplantation, 65% of marrow transplant recipients had deficient CD8+ CTL responses in one study.[104] In immunocompromised patients who cannot mount an effective CTL response, passive transfer of CTLs is an attractive approach to augment cellular immunity. However, early attempts to restore cellular immunity through administration of unselected donor Tcells to marrow recipients was associated with GVHD.[240–242] In an alternative approach, CD3+,CD8+,CD4− CMV-specific CTLs were cloned from CMV-seropositive marrow donors, expanded in culture, and then infused into marrow recipients.[243] Each recipient received four infusions, 1 week apart, in escalating doses. Importantly, the CMV antigen-specific CTLs did not produce GVHD or other morbidity in the recipient.[243] Further studies demonstrated that transferred clones could persist and retain anti-CMV cytotoxic activity for at least 12 weeks following infusion.[244] However, CTL activity declined if recipient anti-CMV CD4+ T cells were not generated. There was no evidence of CMV viremia or disease in any patient receiving CTL therapy.[244] Although adoptive cellular immunotherapy is an attractive approach for prophylaxis of immunocompromised patients, the currently used methods for deriving and expanding donor CTL clones is lengthy, labor-intensive, and costly. However, as this technology improves and becomes more commonplace, transfusion medicine physicians will likely play a significant role in the procurement, processing, and administration of CTL components. For example, studies in a murine model have demonstrated that a rapid and simple method using psoralen-treated MHC-mismatched donor lymphocytes is highly efficacious at clearing CMV infections without causing GVHD following bone marrow transplantation.[245]

RECOMMENDATIONS

The exclusive use of CMV-seronegative blood components for the transfusion of seronegative immunocompromised patients susceptible to transfusion-transmitted CMV remains the standard of care (see Table 46–4). If seronegative units are not available, the evidence suggests that filtered, unscreened components are an acceptable substitute. Although the AABB guidelines state that seronegative and leukoreduced units are equivalent for prevention of transfusion-transmitted CMV,[246] other panels that have reviewed this issue disagree. For example, Swiss clinical practice recommendations consider seronegative units to be the gold standard for prevention of transfusion-transmitted CMV and conclude that leukoreduced units have not yet been proven equivalent for this purpose.[247] A Canadian consensus conference reached similar conclusions when the majority of the panel agreed that seronegative blood components should continue to be provided to at-risk patients despite implementation of universal leukoreduction in Canada.[248] The use of frozen-deglycerolized red cells is also an acceptable alternative to seronegative units, but their preparation is expensive and labor intensive. In contrast, washed red cell and platelet components cannot be considered CMV-safe. The use of IVIg and ganciclovir or other antiviral drugs, are unlikely to be clinically efficacious or cost-effective approaches to preventing transfusion-transmitted CMV.

At the present time, there is no compelling scientific argument for the implementation of CMV NAT screening to prevent transfusion-transmitted CMV. Using the most sensitive and reproducible PCR tests currently available, only about 0.2% of blood donations are found to contain CMV DNA. Furthermore, there are no studies to correlate the risk of transfusion-transmitted CMV with the presence of CMV DNA, although such an association is theoretically attractive. Nonetheless, the potential of CMV NAT to detect seronegative window phase donations, as well as components that retain a residual CMV load postfiltration, remains an interesting possibility to be evaluated. However, implementation of CMV vaccination or virus-inactivated cellular blood components in the future is likely to render the above issues moot.

EPSTEIN-BARR VIRUS (EBV, HHV-4)

The genome of EBV, a gammaherpesvirus, is 172 kbp in length. Two genetically distinguishable types of EBV exist, EBV-1 and EBV-2, as well a number of variants resulting from genomic recombination. In immunocompetent patients primary infection with EBV results in a spectrum of clinical sequelae ranging from an asymptomatic infection to heterophile-positive infectious mononucleosis.[39,249] EBV can

also cause lymphomagenesis, as can the other human gammaherpesvirus HHV-8. EBV is an etiologic agent in endemic Burkitt's lymphoma, AIDS-related lymphoma, post-transplant lymphoproliferative disease (PTLD) and nasopharyngeal carcinoma.[249] After immune-mediated resolution of acute infection, EBV is not completely eliminated but rather achieves a lifelong latent state. The EBV genome is episomal in latently infected B cells, which probably represent the true EBV reservoir in the latently infected host. One in 10^5 to 10^6 B cells is estimated to be latently infected after primary infection. Latent EBV in B cells may undergo sporadic reactivation with subsequent release of infectious progeny virus. Eleven viral gene products are known to be expressed during latent infection, including nuclear antigens (EBNA 1, 2, 3A, 3B, 3C, LP), membrane proteins (LMP 1, 2A, 2B), and noncoding nuclear RNAs (EBER 1, 2).[39] These latent gene products disrupt B-cell regulatory mechanisms, leading to the characteristic polyclonal B-cell lymphoproliferation seen in infectious mononucleosis.

Epstein-Barr virus is transmitted by close contact, and the majority of the adult population (>95%) has been infected with EBV, based on serologic investigations. Seropositive individuals are at risk for reactivation of latent EBV infection if they become immunocompromised (e.g., in the setting of pharmacologic immunosuppression for organ or marrow transplantation).[249] However, the most significant EBV-associated risk is that of primary EBV infection occurring during immunosuppression for transplantation. Primary infection can be community acquired or can result from blood transfusion or transplantation from an EBV-seropositive donor.[249] An important clinical example is pediatric orthotopic liver transplantation, where EBV-associated PTLD has been identified in 10% to 20% of patients immunosuppressed with tacrolimus.[250–252] PTLD encompasses a range of disorders from benign polyclonal B-cell lymphoid hyperplasia to malignant high-grade non-Hodgkin's lymphoma. In pediatric orthotopic liver transplantation, PTLD is a cause of significant morbidity, including graft loss,[253] as well as mortality rates of up to 20%.[254]

Transmission of EBV by blood transfusion can present in a similar manner to classic infectious mononucleosis. As with transfusion-transmitted CMV, viral genotyping has been used to document transfusion-transmitted EBV from a blood donor to a recipient, who subsequently developed EBV-driven PTLD.[255] In most cases of transfusion-transmitted EBV the blood donor has been found to be in the incubation period for infectious mononucleosis with high B-cell viral loads.[256] Although the use of EBV-seronegative blood components may reduce the incidence of transfusion-transmitted EBV, they are difficult to obtain given the high seroprevalence of EBV (Table 46–5). Because EBV is highly B-cell associated and B cells are efficiently removed by blood filtration,[199] exclusive use of leukoreduced cellular blood components for transfusion is likely to decrease the probability of transfusion-transmitted EBV infections in at-risk seronegative patients. This possibility has, however, not been subject to controlled clinical trials.

HUMAN HERPESVIRUS 6 (HHV-6)

HHV-6 was first identified in lymphocytes from AIDS patients with lymphoproliferative diseases and was originally named *human B-cell lymphotropic virus.*[257] However, the primary tropism of HHV-6 is now recognized to be CD4+ T lymphocytes, although it can also infect CD8+ T cells, NK cells, monocytes, macrophages, and megakaryocytes. The linear double-stranded DNA genome of HHV-6 consists of a 143 kb unique segment flanked by 8 to 13 kb terminal direct repeats. Overall, there is 66% sequence similarity between HHV-6 and CMV, the prototypical betaherpesvirus,[258] and greater than 90% sequence similarity between the two HHV-6 variants, HHV-6A and HHV-6B.

Human herpesvirus-6B is the principal etiologic agent of the childhood illness roseola infantum (sixth disease), which presents with a fever of 2 to 5 days' duration followed by a maculopapular skin rash (exanthem subitum) and rapid defervescence.[259] Serologic investigations have demonstrated that HHV-6 is endemic, with 70% or more of children infected by age 1,[260] and over 90% of the population displaying evidence of community-acquired infection during infancy. HHV-6, like other herpesviruses, can persist in a latent state, possibly within PBMCs. In addition to roseola infantum, in immunocompetent individuals there is a weak association between HHV-6 infection and diseases that include heterophile-negative mononucleosis, hepatitis, multiple sclerosis, chronic fatigue syndrome, hemophagocytic syndrome, encephalitis, Rosai-Dorfman disease, Kawasaki disease, Kikuchi lymphadenitis, sarcoidosis, a variety of lymphoproliferative disorders, and rare cases of anemia and granulocytopenia.[261] However, significant problems are rare in immunocompetent individuals. In contrast, immunocompromised patients can experience HHV-6–related complications, including fever, leukopenia, graft rejection,

Table 46–5 **Transfusion Transmission of WBC-Associated Human Herpesviruses**

Virus	Seronegative Recipients	Morbidity following Transfusion Transmission	Special Components for Susceptible Recipients	
			Seronegative	Filtered
CMV	20%–60%	Yes	Acceptable	Acceptable
EBV	<5%	Rare	n/a	?
HHV-6	<5%	Not documented	n/a	?
HHV-7	<5%	Not documented	n/a	?
HHV-8	70%–95%	Not documented	n/a	?

n/a, not routinely available.
?, No clinical evidence for reduction in the risk of transfusion transmission, but possibly effective because viruses are WBC-associated.

interstitial pneumonitis, encephalitis, and marrow suppression.[262–265] Fatal HHV-6 encephalitis has been documented after BMT.[266]

HHV-6 transmission by marrow and solid organ transplantation has been demonstrated.[263,267] However, while PCR analysis of PBMCs showed HHV-6 DNA in up to 90% of blood donors,[268] HHV-6 transmission by blood transfusion has not been definitively documented (see Table 46–5). In analogy with EBV, another highly seroprevalent WBC-associated human herpesvirus, seronegative units are not generally available for transfusion of susceptible recipients. Although filtered components are hypothesized to reduce the risk of transfusion-transmitted HHV-6, clinical efficacy has not been shown.

HUMAN HERPESVIRUS 7 (HHV-7)

Along with HHV-6A, HHV-7 is the only other human herpesvirus with primary tropism for T lymphocytes. HHV-6 and HHV-7 are closely related betaherpesviruses, with an overall 40% sequence similarity. The HHV-7 genome consists of a long unique segment of 133 kb, flanked by single direct repeats of 6 kb on each end.[269] HHV-7, which was originally isolated in 1990 from CD4+ T lymphocytes of a healthy individual,[270] displays much more restricted tropism than HHV-6. In culture HHV-7 can only infect activated CD4+ T cells and the CD4+ cell line SupT1,[271] although in vivo HHV-7 also infects cells of the salivary glands.[272] Infections occur slightly later in life than with HHV-6, but most children are seropositive by age 5. Although a causative role for HHV-7 in pityriasis rosea and a minority of cases of exanthem subitum has been suggested,[273–275] the spectrum of diseases attributable to this virus is still unclear. Because HHV-7 infects CD4+ T cells and viral DNA has been identified in WBCs from 66% of German blood donors,[276] HHV-7 may be transmissible by blood transfusion. The same considerations regarding transfusion transmission of HHV-6 apply to this virus (see Table 46–5).

HUMAN HERPESVIRUS 8 (HHV-8; KAPOSI'S SARCOMA HERPESVIRUS)

HHV-8, a gammaherpesvirus, was originally isolated from Kaposi's sarcoma (KS) skin lesions using representational difference analysis.[277] The HHV-8 genome is approximately 170 kb in size and encodes an estimated 81 ORFs.[278,279] Sequence analysis revealed that HHV-8 is closely related to herpesvirus saimiri and the other human gammaherpesvirus, EBV.[277] As with EBV, HHV-8 can cause uncontrolled proliferation of infected cells. In addition to KS, HHV-8 is also associated with primary effusion lymphoma and multicentric Castleman's disease in patients with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes).[280–282] There is still significant debate concerning the role of HHV-8 in the pathogenesis of multiple myeloma and monoclonal gammopathy of undetermined significance (MGUS).[283,284] If HHV-8 is present in multiple myeloma lesions, it is generally agreed that it is not in the malignant plasma cells, but rather in a subset of surrounding stromal cells. The case has been made that HHV-8 has not yet fulfilled Koch's postulates or Hill's epidemiologic criteria for causality of multiple myeloma.[284]

Human herpesvirus-8 is primarily transmitted through sexual contact, and infection is rare before puberty. The seroprevalence of HHV-8 has been intensely investigated. In most studies, 1% to 11% of the healthy adults in Western countries had detectable anti–HHV-8 antibodies.[285–288] However, when HHV-8 lytic antigens were used as serologic targets, up to 25% of the general population, 90% of HIV-infected homosexual men, and almost all KS patients had detectable antibodies.[289] HHV-8 can be transmitted by infected renal allografts transplanted into seronegative recipients.[290] However, the same study argued against frequent transmission by blood products because no episodes of HHV-8 seroconversion were documented among seronegative recipients of seronegative transplants who received blood transfusions. Nonetheless, HHV-8 DNA has been identified in PBMCs of 55% of patients with KS[291] and in the blood of some renal transplant patients.[292] An HHV-8 seroprevalence of 35% to 82% has been reported in healthy non–HIV-infected individuals in central Africa.[286,287,289] Approximately 22% of apparently healthy central African blood donors had low levels of WBC-associated HHV-8 DNA, compared to about 0 to 2% in healthy Europeans.[291,293,294] Furthermore, there is an association of HHV-8 infection and intravenous drug use in women, independent of sexual activity, which also argues for the possibility of blood-borne transmission.[295]

Recent studies lend support to the possibility that HHV-8 is transfusion-transmitted, albeit at low rates. In Uganda, HHV-8 seropositivity positively correlated with number of transfusions, with a calculated 2.6% risk of infection per transfused blood component.[296] Using archived samples from Frequency of Agents Communicable by Transfusion study (FACTS), a repository created before the widespread use of leukoreduction, 2 HHV-8 seroconversions were identified among 284 seronegative transfusion recipients (risk per component, 0.082%).[297] Although the current risk of transmitting HHV-8 by blood transfusion is unclear, the clinical issues associated with providing HHV-8 "safe" blood components are more similar to those associated with CMV than with EBV, HHV-6, or HHV-7 (see Table 46–5). Thus, it may be possible to provide either HHV-8 seronegative units or filtered components to abrogate the risk of transfusion-transmitted HHV-8. However, further investigations will be necessary to validate the efficacy and usefulness of these approaches.

Chapter 47

Bacterial Infections: Bacterial Contamination, Testing, and Post-Transfusion Complications

Sandra M. Ramírez-Arcos • Mindy Goldman • Morris A. Blajchman

Bacterial contamination of blood components has been recognized as the oldest and most prevalent current transfusion-associated infectious risk.[1–3] Although the risk of acquiring transfusion-transmitted viral infections has decreased substantially over the past 20 years, cases of life-threatening reactions resulting from bacterial contamination continue to be reported.[2–8] Prospective studies have indicated that the range of clinical severity is very wide and that mild reactions are often misidentified as febrile nonhemolytic transfusion reactions.[3,9–16] Although severe reactions are relatively uncommon, bacterial contamination of blood products is currently the major microbiologic cause of transfusion-associated morbidity and mortality, with platelets being the blood product most susceptible to bacterial contaminants.[2,3] Because platelet components are stored at room temperature, they offer the most favorable medium for bacterial growth; thus, bacterial contamination has been the limiting factor in decreasing the permissible length of platelet storage. Although they are most common with platelet components, reactions associated with contaminated red blood cells (RBCs), plasma, cryoprecipitate, and albumin have also been reported.[2,17–20] Moreover, bacterial contamination remains one of the residual complications of autologous transfusions.[21–24]

Many methods have been developed to detect bacterial contamination in blood products, each with differing sensitivity and specificity. These methods range from simple visual inspection to sophisticated molecular methods.[25,26] Changes in every step of blood component preparation, from donor screening to phlebotomy procedures, pretransfusion bacterial detection, as well as improved component production and storage, have been proposed to decrease the frequency of bacterial contamination. In several countries, routine pretransfusion culture of platelets has been implemented, in some cases to permit extended storage of up to 7 days before transfusion.[3] Finally, methods of photochemical inactivation of bacteria are under active development, which may eliminate the problem of bacterial contamination in the future.[3,27,28]

PRESENTATION AND PREVALENCE

Red Blood Cells

Sepsis associated with the transfusion of bacterially contaminated RBCs is regarded as a very rare event, with a prevalence of significant clinical outcomes of 1 in 250,000.[3] This low prevalence is due to poor viability of most bacteria in whole blood or RBCs stored at 1°C to 6°C. However, psychrophilic pathogenic gram-negative bacteria such as *Yersinia enterocolitica* retain viability and replicate under RBC storage conditions. Infections caused by such bacteria are associated with a mortality rate of approximately 70%.[2,7,8,19] Septic reactions are characterized by temperatures higher than 38.5°C, rigors, and hypotension beginning during the transfusion. Nausea, vomiting, dyspnea, and diarrhea occur in a significant number of cases; septic shock, oliguria, and disseminated intravascular coagulation are also frequent complications.[29] Anesthetized patients may present with hypotension, oliguria, and excessive bleeding. The acute reactions are thought to be caused by the concomitant infusion of bacterial endotoxin followed by the massive release by the recipient of cytokines (e.g., tumor necrosis factor-α) that are important mediators of the pathogenesis of shock.[30,31] In most reported transfusion-associated septic reactions, the RBCs had been stored for longer than 21 days and therefore likely carried a high bacterial and endotoxin load.[29]

There have been few prospective studies examining the frequency of bacterial contamination in patients receiving RBC transfusions. In two consecutive studies done at the Dana Farber Cancer Institute, cultures of RBCs and recipients involved in transfusion reactions demonstrated a possible contamination rate of 1 in 38,465 units transfused, for a rate of 2.6 per 100,000 transfusions.[11,14]

Although RBCs are not routinely screened for bacterial contamination, bacterial testing of whole blood-derived platelets (WBDPs) increases the microbiologic safety of RBC components in an indirect way, because most RBC units associated with contaminated WBDP units will generally not be transfused. In some European countries, 100% of WBDP units are screened for bacterial contamination, resulting in a significant decrease in transfusion of contaminated units.[32] There is some evidence that approximately 40% of RBC and plasma units associated with bacterially contaminated WBDPs test positive when screened.[3]

Apheresis Platelets and Platelet Concentrates

Because platelets are stored at 22 ± 2°C, they provide a hospitable culture medium for a wide variety of bacteria; therefore,

bacterial contamination poses *the* major microbiologic cause of adverse transfusion reactions to platelet components.

Clinical sequelae of transfusing bacterially contaminated platelets are variable and may be acute or delayed, depending on the severity of the recipient's medical condition, the type and concentration of the contaminant bacteria, and the timing of transfusion.[2] Because only the most severe reactions are likely to be recognized and reported, case reports represent the severe end of the clinical spectrum of transfusion reactions associated with bacterial contamination. Prospective studies demonstrate that the majority of recipients of contaminated platelet transfusions develop either no symptoms, or fever and chills with no clinical sequelae.[9,11–14] These reactions may be clinically indistinguishable from febrile nonhemolytic transfusion reactions.[33,34] Despite the introduction of routine bacteriologic screening, many platelet units are released into inventory and transfused without any reaction, and are then found to be contaminated.[3]

Reports on the prevalence of bacterial contamination in platelets are variable due to the use of different methods for bacterial detection. It is estimated that 1 in 1000 to 1 in 3000 platelet units are bacterially contaminated.[2,3,35] Clinical sepsis due to the transfusion of bacterially contaminated platelets occurs in approximately 1 in 25,000 transfusions, and a fatality is expected in approximately 1 in 60,000 transfusions.[3,35] Fatality rates vary in different countries, most likely due to the presence or absence of adequate hemoviligance systems and an environment of active reporting.

Fresh Frozen Plasma and Cryoprecipitate

Because plasma and plasma derivatives are stored frozen, they are less likely to contain clinically significant numbers of bacteria at the time of transfusion. However, there are reports of patients who developed wound infections, endocarditis, or septicemia several days after receiving cryoprecipitate or plasma that were thawed in bacterially contaminated water baths.[36,37] As indicated, approximately 40% of the co-components of contaminated platelet units, including plasma, have been also found to be contaminated.[3]

Peripheral Blood Stem Cells

It has been found that the incidence of bacterial contamination of untreated peripheral blood stem cells ranged from 0.23% to 4.5%, increasing by an additional 1% after cryopreservation.[1,38,39] The organisms usually implicated are part of the normal skin flora, including coagulase-negative staphylococci, *Propionibacterium acnes*, and α-hemolytic streptococci, although in some cases bacteria of potential clinical significance such as *Staphylococcus aureus* and *Enterobacter cloacae* can be isolated.[1,38,39] No adverse clinical sequelae from the infusion of culture-positive collections have been reported, probably because most recipients were receiving prophylactic antibiotic treatment at the time of the stem cell infusion.[38,39]

Determinants of Clinical Severity

The clinical consequences of transfusing bacterially contaminated blood components range from minimal or no reaction to fatal septic shock and death. The bacterial and recipient characteristics known to influence the clinical severity of a transfusion-associated infection include: the bacterial species present in the blood component, with gram-negative bacteria the cause of the most severe reactions due to endotoxin production; the concentration and growth rate of the bacterial contaminant; and recipient characteristics such as underlying disease, status of the immune system, and ongoing treatment with antimicrobial therapy.[29,35]

BACTERIA IMPLICATED

Red Blood Cell Concentrates

Yersinia enterocolitica is responsible for approximately 56% of the reported cases of RBC-associated sepsis, with a case-fatality rate of approximately 60%.[7,8,40–42] This pathogen is usually acquired by the ingestion of contaminated foods, producing mild symptoms such as abdominal pain and diarrhea. The frequency of *Y. enterocolitica*–associated RBC septic reactions varies markedly in different geographic locations and in different time periods. For example, the incidence of transfusion-transmitted *Yersinia* infections in New Zealand is 80 times higher than in other countries, including the United States.[1]

Because *Y. enterocolitica* lacks siderophores, growth is enhanced in an iron-rich environment such as stored RBCs. This has been noted particularly for *Y. enterocolitica* serotype O:3, whose growth rate is proportional to the availability of iron in the environment and which renders it the most common *Yersinia* pathogenic type.[1,43] Data from spiking experiments with *Y. enterocolitica* show that a lag phase of approximately 2 weeks is followed by exponential growth. A concentration of 10^9 organisms per millimeter is usually reached after 4 weeks of RBC storage, with a parallel rise in endotoxin level.[44]

A changing trend in the bacterial species that contaminate RBCs has been noted in the past few years.[2] Other RBC contaminant species include *Serratia* spp., *Pseudomonas* spp., *Enterobacter* spp., *Campylobacter* spp., and *Escherichia coli,* which also have the potential to cause endotoxic shock in recipients.[1] *Serratia liquefaciens* has been increasingly recognized as the cause of transfusion-associated sepsis with a high mortality rate.[2,45] *Pseudomonas aeruginosa* and other *Pseudomonas* spp. have also been involved in sepsis transmitted by RBC transfusions.[2,19,44] The plant pathogen *Pantoeae agglomerans* (previously known as *Enterobacter agglomerans*) has been implicated in two fatal post-transfusion sepsis cases.[47]

There have been four reports of septic shock related to the contamination of autologous RBC units; all four patients survived.[21–24] In retrospect, in the three cases involving *Y. enterocolitica*, the donors had experienced gastrointestinal symptoms in the days before or after their autologous donation.[21,22,24] In the one case involving *Serratia liquefaciens*, an infected toe ulcer may have been the source of a transient bacteremia at the time of the implicated autologous blood donation.[23]

Apheresis Platelets and Platelet Concentrates

In both case reports and prospective studies, the majority of organisms isolated in platelet-associated bacteremic episodes are part of the normal skin flora.[9–17] *Staphylococcus aureus*, coagulase-negative staphylococci, aerobic and anaerobic

diphtheroid bacilli, streptococci, and gram-positive bacilli are the most frequently isolated organisms.[1] On rare occasions, gram-positive bacteria such as *Streptococcus bovis* that are neither part of the normal skin flora nor environmental contaminants have been implicated in infections resulting from transfused platelets.[48,49]

Although most fatal cases of the bacterial contamination of platelets involve gram-negative organisms,[2,3,20] fatalities due to transfusion of platelets contaminated with gram-positive bacteria have been reported in North America and in Europe. Coagulase-negative *Staphylococcus lugdunensis* was recently involved in a fatal bacterial infection associated with the transfusion of a platelet unit.[50] The U.S. Food and Drug Administration (FDA) reported that in the United States, from 1976 to 1998, 41% of the transfusion-associated septic fatalities were caused by gram-positive organisms, including 10% of the fatal outcomes caused by coagulase-negative staphylococci.[20] A combined summary of the data issued by the United Kingdom (UK) Serious Hazard of Transfusion (SHOT) hemoviligance program, the French BACTHEM study, and the U.S. Bacterial Contamination of blood (BaCon) study showed that 12% of fatalities were due to transfusion of platelets contaminated with gram-positive normal skin flora; 8% of these bacteria were coagulase-negative staphylococci.[20]

Transfused microorganisms have also been involved in delayed post-transfusion illnesses. Seven patients who received contaminated platelet units containing *Salmonella* did not develop symptoms until 5 to 12 days after transfusion. All units had been obtained from the same donor, who had an occult chronic osteomyelitis.[51] Although not always possible, bacterial infections caused by contaminated platelets can be discovered in retrospect. During the investigation of two sepsis cases due to RBCs contaminated with *S. liquefaciens*, it was discovered that the associated platelet units had also been the cause of fatal sepsis and bacteremia in the recipients.[45]

Fresh Frozen Plasma and Cryoprecipitate

Burkholderia cepacia (previously known as *P. cepacia*) and *Pseudomonas aeruginosa* are environmental organisms that grow optimally at 30°C. They have been isolated from cryoprecipitate and plasma thawed in contaminated water baths.[36,37] *Enterobacter cloacae* has also been implicated as a contaminant of human albumin that caused septicemia in two patients. Cracked glass bottles were the suspected cause of this contamination.[52]

INTRACELLULAR BACTERIA: RICKETTSIAS AND SPIROCHETES
